The question next presents itself, Is the binoxide of manganese an equally efficient emmenagogue with the permanganate of potassium? On this point published testimony is not as yet abundant. In the article of Drs. Ringer and Murrell, from which we have quoted, the answer was, as we have seen an affirmative one. Dr. Franklin H. Martin in a recent communication [1] refers to the binoxide as having proved, on account of its insolubility, almost inert. Dr. T. G. Thomas, on the other hand, informed me, a few days since, in answer to my inquiry on the subject, that the binoxide, in the form in which he employs it, has seemed to be equally efficient with the permanganate, and much better tolerated by the stomach.

Dr. Franklin H. Martin, of Chicago, in his very valua ble contribution to the literature of this subject, first referred to, states that his observations have led him to regard manganese in any form as a direct stimulant to the uterus and its appendages; that though it acts as a general tonic it has a special predilection for those organs. He suggests that it may exert that influence by acting as a direct vaso-motor nerve stimulant to the vascular system of the parts, or by stimulation of the sexual nerve ganglia, or even possibly of the sexual nerve-centres. He calls attention to the fact that as long ago as in 1868 Dr. Broadbent, after experiments performed by him, and recorded in the "Proceedings of the Clinical Society of London" for that year, says: "Manganese seemed to have a special influence in promoting the return of the catamenia, and nickel a special property of checking leucorrhoea."

Mode of administration.—The administration of the permanganate in solution is, as we have seen, ineligible, on account of its liability to cause gastric irritation, and in compressed tablets has been found nearly as much so; although that tendency is shared in a minor degree by all other modes of employing it.

In making it into pills with ordinary excipients there has been found to be liability to decomposition and combustion. Ringer therefore suggests, as a suitable basis for the composition of pills, kaolin and cerate of petroleum in equal parts.

Mr. Angelo has lately shown me specimens of tablets which he prepares with cocoa-butter. They are pleasant to take, will dissolve readily in the stomach, and may, perhaps, be found preferable to the form last mentioned. There is, however, probably no better mode of administering the remedy than in gelatine capsules.

The permanganate is commonly best tolerated by the stomach when taken soon after meals.

Binoxide of manganese may be given, in pills or capsules, in doses of from two to four grains three or four times a day.

The administration of manganese, in either form, in amenorrhœa should usually be begun about one week before the time of the expected menstruation. Should it then fail of effect its use may be continued through the interval to the next one, or it may be suspended and resumed at the corresponding period of the following month.

For those patients, at least, who are unable to swallow pills or capsules, the following suggestion of Dr. Franklin H. Martin [1] may be found valuable. Of a twenty per cent. solution of the oleate of manganese let one drachm be applied to the abdomen or the inner surface of the thighs of the patient, and its absorption promoted by vigorous rubbing with the hand until it

[1] [illegible]

has disappeared. In cases of amenorrhœa this is to be done every night for a week preceding the time of the expected menstruation. In cases of menorrhagia or metrorrhagia it may be applied in the same way, but in smaller quantities, until the desired effect is produced.

The principal questions for consideration in connection with this topic are the following:

I.—Is permanganate of potassium an efficient emmenagogue in certain forms of amenorrhœa?

II.—To what forms is it applicable?

III.—Is it also remedial to certain forms of dysmenorrhœa, menorrhagia, and metrorrhagia?

IV.—To which of its component elements is this action due?

V.—What is the nature of this action? Is it specially exerted upon the organs of menstruation, or is its effect upon them only incidental to its general action? Is it mainly through the blood or the nervous system? If the latter, in what way?

VI.—Does the permanganate of potassium, or manganese in any form, improve the blood condition in anæmia and chlorosis?

VII.—Is the binoxide of manganese an efficient therapeutic agent?

VIII.—What are the best modes of administering the salts of manganese?

I am confident that the imperfections of the preceding paper will be condoned in consideration of my having been kindly permitted to present to the Section, in connection with it, the following very interesting statements on this topic from the large experience of Drs. Fordyce Barker and T. G. Thomas:

"DEAR DR. BILLINGTON: I regret extremely that a previous engagement, from which I cannot get free, will prevent me from accepting the courteous invitation of Dr. J. C. Peters, the chairman of the Section of Materia Medica and Therapeutics of the Academy of Medicine, and of the pleasure of listening to your paper on the 'Treatment of Amenorrhœa.'

"I am happy, however, to comply with your polite request to give you 'a *résumé* of my experience' in the use of the permanganate of potash in this affection.

"For many years, as you perhaps may know, in my lectures to medical students I was accustomed to express my incredulity as to whether any article, known in materia medica, could be regarded as possessing the property of a direct emmenagogue. Of course, in common with all other physicians who have been some years in practice, I have had my full share of experience in the use for this purpose of iron, aloes, myrrh, savine, rue, and other agents of this character, and I have often seen menstruation return, apparently as a consequence, but I never was convinced that this result was due to a direct influence on the uterus or its functions. For some fifteen years or more, I found more success in the use of capsules of apiol, two or three times a day, commencing three days before the menstrual period. But this often failed, and I was never able to determine the precise conditions where it would be successful or where it would fail.

"I therefore only prescribed it empirically, hoping for success.

"I think that it was about five years ago that I was told by a physician in London that Dr. Sidney Ringer had found the permanganate of potash a very efficient emmenagogue. I was prepared to receive the statement favorably, from the well-known property of the different preparations of potash of rapid diffusion through the blood, and from my experience in the great value of the chlorate of potash in the treatment of chlorosis associated with amenorrhœa, as in my clinical lectures I taught for many years.

"The past four years I have used the permanganate of potash exclusively when an emmenagogue is indicated, except in a limited class of cases of sudden suppression, to which I will subsequently refer.

"As you will doubtless discuss fully the action of the permanganate of potash in its scientific aspect, I will restrict what I have to say to my clinical experience; and this can be more clearly illustrated by referring to groups of cases.

"I first prescribed the permanganate in September, 1881, to a lady, thirty-six years of age, who had resided in Europe for the previous nine years. Some two years before an obscure form of disease of the nervous system followed a severe moral shock, and she was under the treatment of Dr. Brown-Séquard for several months. She finally became insane, and was in a *maison de santé* in Paris for ten months.

"She left this institution in March before I saw her, rational, but morbid, irritable, and so suspicious as to make the life of her family a burden, particularly several days each month. Her general health was pretty good, but she had not menstruated for twenty months.

"While I gave general directions as to her health, in the use of laxatives, diet, and open-air exercise, etc., I prescribed for the amenorrhœa two grains of the permanganate of potash three times a day. In four days menstruation came on and lasted three days. This was followed by such an improvement in her condition, physical and moral, that I ceased my attendance. Seven weeks after I was again called, and found her very nearly in the same state as at my first visit. She did not menstruate the previous month. The permanganate was again repeated, with the same happy result. This treatment was resumed the three subsequent months. Since then this lady has been physically well and morally happy, making her family also happy.

"This success led to a further trial of this agent, and since that time I have used it in comparatively a large number of cases. I say 'comparatively,' because I think no man can say that he has treated really a large number of cases of amenorrhœa.

"In order more clearly to illustrate my views, I will divide the cases which I have treated with this remedy into three groups, mentioning them in the order of their frequency.

"First. Young ladies between the ages of fourteen and nineteen, who come from the country 'to finish their education.' Home-sickness, entire change of life in its habits and associations, overtax of their brain-power from the ambition of themselves or their teachers to accomplish more in a given time than they ought to attempt, not unfrequently leads to an arrest of menstruation. I see ten or fifteen such cases every winter.

"Second. Ladies, both young and married, who suffer severely from sea-sickness, that have left some European port within a few days of the menstrual period. With such, amenorrhœa of longer or shorter duration is almost sure to follow. I am consulted by at least eight or ten such every year.

"Third. Ladies, between thirty and forty years of age, generally married, some of whom have borne children, who rapidly begin to gain flesh, grow stout, and at the same time menstruation decreases in both duration and quantity, until at last it is only a mere pretence. This is generally attended with annoying nerve disturbances, pelvic weight, sometimes hemorrhoids, and often with moral depression from the apprehension of growing old prematurely.

"Now it requires some moral courage on my part for me to boldly avow that, never, where in either of the above classes of cases I have prescribed the permanganate of potash, have I *known* it to fail.

"But this assertion requires explanation. The cases of this kind for which I have prescribed have, with but two exceptions, not occurred in my family practice or that of Dr. A. A. Smith, but have come to me for the special treatment of amenorrhœa, many of them from out of the city, and from other parts of the country.

"In all prescriptions for the permanganate I write to the druggist, 'Return the prescription,' and direct the patient to continue the medicine, if necessary, for at least three months, and especially urge her to report to me, either personally or by letter, if the end be not accomplished. Many such have reported that all was right; many others from out of town I have not heard from; and perhaps I am wrong in believing that the treatment was successful. I must add, that with this specific treatment I endeavored not to neglect any other measures necessary to keep up a healthy and regular action of other functions.

"I will add, in regard to the third class in my group, that every patient was a resident of this city. I presume that every medical man who has been long in practice has met with some such. In all these I have known, from personal interviews, the result; that there has been a satisfactory return of menstruation, although in two cases it was necessary to continue the remedy for five months. In all there has been entire relief of the cerebral, pelvic, and, in some, thoracic nerve disturbances, cardiac and pulmonary. One was quite cured of a periodic asthma from which she had suffered monthly for three years.

"Of course I never prescribe this agent in cases where the amenorrhœa is due to some grave constitutional disease; nor do I rely on it for the relief of sudden suppression, due to cold, moral shock, or an acute disease. In this class I think that pulsatilla, opiates, and local agents, such as fomentations and large hot rectal enemas, are generally successful.

"In my early experience I found great difficulty in getting the permanganate put up by druggists in such a way that patients could take it without great repugnance, and it often produced severe gastric pain, from its rapid decomposition. Mr. Angelo for a time put it up for me in a peculiar capsule, which did better than anything else, so far as the taste is concerned, and the pain was prevented by swallowing immediately a half tumbler of water, not cold. Latterly I have found two-grain tablets do quite as well, if the same quantity of water is swallowed at once. Fraser & Co. have recently prepared it in grain pills, but I have not yet had the opportunity of trying them.

"That all may judge how much weight should be attached to my clinical experience, I will add that I find on the stubs of my office prescription-book I have prescribed the permanganate of potash forty-four times since November 17, 1884, which exactly represents the number of cases of amenorrhœa of the groups mentioned before, as in this time I cannot recall an instance where I have made a domicile visit for this disease.

"I think you may well congratulate the Section that I am not able to be present at the meeting, as they will be saved the bore of a speech—one talks so much more diffusely than he writes. Very sincerely yours,

"FORDYCE BARKER.

"24 EAST THIRTY-EIGHTH STREET, February 14, 1886."

"MY DEAR DR. BILLINGTON: You ask for my experience with manganese and its salts as an emmenagogue. I have used them freely ever since they were first recommended by Ringer.

"Thus far no perfect emmenagogue has been discovered, but I regard manganese as the best that I have met with. It should be styled a regulator of menstruation rather than a pure emmenagogue, for it is useful in absence of the menses, irregularity of their recurrence, and even in excess of flow.

"The preparation which I now employ is McKesson & Robbins' pills of the binoxide of manganese. Of this preparation I give two grains three times a day throughout the month and during the period.

"I also employ manganese in chlorosis and anæmia, and I think that by its use I obtain better results than I have heretofore done by iron.

"Knowing how apt the medical mind is to give way to enthusiasm with reference to new remedies I have spoken guardedly of this one. But I do not wish to 'damn it by faint praise.' While I recognize that it is like all other medicines, very uncertain in such cases as I have mentioned, I look upon it as a very valuable addition to the Pharmacopœia.

"Sincerely yours,

"T. GAILLARD THOMAS.

"294 FIFTH AVENUE, February 9, 1886."

A BIOGRAPHICAL SKETCH OF THE LATE ALFRED C. POST, M.D., LL.D.[1]

BY JOHN C. PETERS, M.D.,

NEW YORK.

HORACE tells us it is well sometimes to plunge boldly into the middle of the things we have to tell. In accordance with this advice I will commence with the middle period of Dr. Post's life, which also marks the commencement of his membership in this Society. He joined it in 1851 when he was forty-six years of age. He became our president in 1861, when he was fifty-six years old, and in his very prime, although that would seem almost great age for the majority of men.

He had been preceded in the presidency by Drs. John A. Swett, Willard Parker, James R. Wood, Thomas M. Markoe, William H. Van Buren, C. E. Isaacs, John T. Metcalfe, Robert Watts, E. R. Peaslee, John C. Dalton, and Ernst Kracowizer. Of these only Drs. Markoe, Metcalfe, and Dalton are left with us. Two are in excellent health, and long may they remain so. The other is an invalid.

Dr. Post was elected by the votes of Drs. Isaacs, Batchelder, Gilman Bolton, Willard Parker, McNeven, Bowen, and Robert Watts (7), who have passed away from us, and by those of Sayre, McCready, Van Arsdale (?), Purple, George F. Shrady, and Alonzo Clark (6), who are still with us.

In those times, twenty-five years ago, the attendance at the Society occasionally fell as low as six or seven. Often only ten or fifteen members were present, but frequently we had twenty or thirty, and occasionally from thirty to forty-eight, which I believe was the highest number.

The modest annual dues were still $1, but the first microscope, costing $150, was purchased in 1851. It was a good one, furnished with lenses by Nachet, of Paris, and Powell & Leland, of London. Dr. Post was already working with the microscope and specimens were often submitted to him for examination. But Drs. Dalton, H. B. Sands, Gouley, Draper, and others, were the principal microscopists, although everybody was discovering fibro-plastic tumors and caudate cells.

During the ten years that Dr. Post was a member of this Society before he became president, his contributions were already characteristic of what was to come in later years. He exhibited the results both of the boldest and most delicate operations, such as extirpated thyroid, parotid, and cervical glands, rectums, and ovarian tumors, exsections; he made artificial anuses, opened abscesses of the liver, performed tracheotomy for croup, removed parts of the omentum in strangulated hernia, large and small urinary calculi, and then came down to little slivers of bone, remarkable only for their small size and the great amount of long-continued irritation they had caused; also calculi, so small that they could scarcely be handled, yet had caused much suffering for five or more years; and little supernumerary fingers and toes, small encysted tumors of the scalp, and tiny subcutaneous neuromatous tumors. No operation was too great or too small for him.

During Dr. Post's presidency in 1861, one hundred

[1] Read before the New York Pathological Society, February 24, 1886.

and thirty-five specimens were presented before this Society. The principal exhibitors were Gurdon Buck, A. C. Post, Foster Swift, Voss, George T. Elliott, Sewell, Lente, J. R. Wood, Willard Parker, D. S. Conant, and William H. Van Buren, who have been taken away from us; and Alonzo Clark, A. L. Loomis, J. C. Dalton, George A. Peters, Dr. Finnell, Dr. Baner, J. T. Metcalfe, H. B. Sands, Robert Weir, William H. Draper, J. Lewis Smith, George F. Shrady, A. Jacobi, D. B. St. John Roosa, Cornelius R. Agnew, Lewis A. Sayre, Drs. Briddon, and Austin Flint, whom we still have with us.

Dr. Post's communications in 1861 did not differ much from those already recorded. Dr. Alonzo Clark was still holding that great lead in the Society which he had maintained so long, and was still developing his views about large hearts, perforations of the vermiform appendix, thrombosis of the arteries, diseases of the suprarenal capsules, and Bright's disease. Drs. Loomis and Draper were exhibiting specimens of abdominal tumors, fatty degeneration of the heart, abdominal and thoracic aneurisms, pericarditis, and tumors of the cerebellum.

Dr. Sands was performing some of his brightest operations, and discovering fibro-nucleated tumors. Drs. Roosa, Agnew, and Shrady were hospital surgeons, reporting intracapsular fractures of the femur, ruptures of the spleen, ulcerations of the bowels, and scirrhous mamma.

Dr. Jacobi and J. Lewis Smith were discussing diseases of infants, and cases of intussusception and tracheotomy.

George T. Elliott was reporting ovarian tumors, cancers of the uterus, fatty placentas, and infant monsters caused by their mothers being frightened by elephants.

Drs. Kracowizer and Voss were teaching us about dermoid cysts of the uterus, neck, and other parts; obstructions of the coronary artery, osteo-myelitis, osteo-sarcomas, etc.

This will serve to give a faint outline of the general labors of the Society in 1861, which, with the exception perhaps of the microscopical work, was almost as good as ever has been done in it. Still, I may add that Drs. J. R. Wood, Sayre, and George A. Peters were re-and excecting bones and joints, tying for popliteal and other aneurisms, reporting diseases of the periosteum, varied with records of ruptures of the appendix vermiformis, cancers of the stomach, and trephinings of the skull.

Dr. Post's presidency was marked by two sad events. The first was the death of our well-beloved President, Dr. Charles E. Isaacs. The Society adjourned in respect for his memory, which was very unusual then, and has been since, and drew up resolutions expressive of its sincere regret. Guided by hard scientific instincts, this Society scarcely ever takes any notice of the deaths of its officers or members, however distinguished they may be, unless their bodies also furnish interesting pathological specimens.

The character and services of Drs. Isaacs and Post were so similar, and the proceedings of this Society were so sincere and dignified at the death of Dr. Isaacs, that they may well be repeated here. Like Dr. Post, Dr. Isaacs was a distinguished anatomist, surgeon, and pathologist. He lived in Brooklyn, and a joint special meeting was held by the Pathological Society and Academy of Medicine in the Mayor's office there, to take proper action about his decease and to attend his funeral.

"Dr. William H. Van Buren offered the following preamble and resolutions:

"WHEREAS, It has pleased Almighty God to remove from among us our beloved and respected colleague and late President, Dr. Charles E. Isaacs, whose extensive learning, high professional attainments, and singular purity of character have won for him the warm personal regard of all who knew him; it is therefore, in respectful tribute to his memory,

"*Resolved*, That in the decease of Dr. Isaacs these Societies have lost one of their ablest and most industrious members, whose anatomical and pathological researches have enriched our transactions with some of their most valuable papers, and placed their author in the foremost rank of the cultivators of medical science.

"*Resolved*, That in the performance of the practical duties of his profession, in which he was no less honored and successful than in the cultivation of science, we recognize the conscientious fulfilment of obligations and the considerate skill which have so justly gained for him his high position in this city and the devoted attachment of his many friends, to whom and to his immediate family we respectfully and sincerely tender our great sympathy for their severe loss.

"*Resolved*, That whilst we admire the learning, and respect the ability of our departed colleague, we recognize also that he possessed in an eminent degree the qualities of the amiable and honorable Christian gentleman: as gentle in manner and pure in thought as a woman and yet possessing all the courage and energy of a man: considerate to the feelings of all; speaking slightingly of none; singularly diffident of his own high powers, and yet employing them earnestly for the benefit of others, rather than for himself.

"It may be said of him with literal truth

> [illegible]
> None named him but to praise.

"(Signed) GEORGE F. SHRADY, *Secretary*."

A more just and elegant tribute was never paid to any member of this Society, and it applies as well to Dr. Post as to Dr. Isaacs. I am glad to revive the memory of Dr. Van Buren also.

The second sad event was the death of Dr. Post's oldest son, in sorrow for which the Society adjourned. Afterward Dr. Post filled the chair at every meeting during his presidency, thus setting an example of fortitude and respect for duty which is characteristic of conscientious and scientific men.

During Dr. Post's presidency in 1861, the so-called great unpleasantness, or the late huge civil war broke out. From that time till 1865 Dr. Post went down from time to time, with many other New York surgeons, to take care of the wounded of both armies. His religious side had long been dominant, and we can imagine him silently praying with his favorite Horace:

> Our new-raised troops be thy peculiar care
> Who to the dreadful South our banners bear.

He was at that time especially impressed with the benefits of bromine in hospital gangrene, originally suggested by one of our founders, Dr. Middleton Goldsmith.

At this middle period of his life Dr. Post had been surgeon to the New York Hospital since 1836, or from the time he was thirty-one years old. He was one of the founders, in 1843 I believe, of the medical department of the University of the City of New York; an active member of the New York Medical Missionary Association; one of the directors of the Union Theological Seminary, and an elder in the Church of the Covenant. Hence it was with no irreverent spirit that he said the two things he enjoyed most in this life were a surgical operation and a prayer-meeting.

His religion was never obtruded on his colleagues, but he often made pleasant little hymns for young children, and conducted the simple religious services in the Nursery and Child's Hospital. Although often a little grim, he could enjoy paraphrases of Watts' Hymns, such as:

> He forms our surgeons for the field
> With all their dreadful skill;
> He gives them awful knives to wield,
> And makes their hearts of steel.

It may be said with almost literal truth that Dr. Post never passed his middle and prime age until he was nearly eighty years old. It was only a few months before

his decease that his friends detected signs of failing health and strength. Up to that great age, like the patriarch of old, his eyes were so little dimmed, and his natural force so little abated, that we rarely realized he was an old, old man. During the last ten years of his life he was performing some of the most skilled and delicate feats of plastic surgery, and only four months before his death he performed an ovariotomy in forty-five minutes as successfully and skilfully as only much younger men can do, and at a later period extirpated the rectum, an operation requiring an hour and a half, and then showed no signs of fatigue. If he had not been taken away by sudden and sharp sickness he would have lived many years more, and might have gone on operating until he was near ninety, and certainly would have been praying till the last moments of his life. *Laborare est orare.*

Horace also says, after having exhausted the middle and end of a history or biography it may be well to commence at the beginning.

Dr. Post commenced his classical education in Columbia College when he was only fourteen years of age. His memory was something remarkable and apparently never at fault. He was always as ready to give the derivation of a word as he was to perform a major or minor operation, and he never forgot, but always increased his store of the Greek, Latin, French, and German languages. He could have said

> The Greek and Roman languages are mine,
> With all their curious words and strains sublime.

He commenced his medical studies with his uncle, the celebrated Dr. Wright Post, in 1822, and graduated from the College of Physicians and Surgeons in 1827, after five years' study. He then went to Europe for two years, visiting London, Edinburgh, Paris, Berlin, and Vienna, to complete his medical and surgical studies.

He was the second American medical student who went to Vienna and studied pathological anatomy under Rokitansky. Dr. Gurdon Buck was the first, and John C. Peters the third. I brought back portraits of Rokitansky and letters of remembrance from him to Drs. Buck and Post in 1843.

The history of Dr. Wright Post is nearly like that of Dr. Alfred C. Post. Dr. Wright Post was one of the most accurate anatomists and accomplished surgical men that New York has ever produced. A beautiful portrait of him has long hung, and still hangs, in the lower hall of this College. He was born in 1766, so that the professional services of the Post family have stretched well over a century of time, and are still upheld worthily by Dr. George E. Post, son of Alfred, now long a medical missionary in Syria.

Dr. Wright Post had been a student with Dr. Richard Bailey, at that time one of the most celebrated and skilful surgeons in New York, whose memory is never omitted in the medical histories of this city.

Dr. Wright Post graduated and went to London in 1784, remaining two years and a half, coming back an excellent anatomist and an equally good surgeon. Dr. Valentine Mott says his skill with the scalpel and bistoury was masterly. He commenced at once to lecture on anatomy in the New York Hospital, and in 1792 became Professor of Surgery in Columbia College. He then went again to England and returned with a large and rare collection of anatomical specimens, which remained the best in this country till 1823, and parts of which are still in this college.

He also came back with a thorough knowledge of operative surgery and soon attained the highest rank in this city. Even his early operations were marked, not only by great mechanical skill, but also by that freedom of thought and action which a minute acquaintance with anatomy and of the principles of surgery alone can give. He tied the femoral artery in 1796, and soon performed two successful operations for carotid aneurism. He was the second to tie the external iliac for inguinal aneurism; and he was absolutely the first in this country to tie the subclavian on the scapular side of the scaleni muscles for an aneurism high up in the axilla. He was also the first to give large doses of opium in peritonitis and other inflammations of serous membranes.

Dr. Wright Post lectured till 1813, or more than twenty years, with Dr. Bailey on surgery, Samuel L. Mitchell on chemistry, Hammersley on theory and practice, and Hosack on materia medica. All these are still household medical names in New York.

In 1813 the medical faculty of Columbia College was united with the College of Physicians and Surgeons, and Dr. Wright Post became associated with Drs. John Augustine Smith, MacNeven, John Bard, De Witt, Stringham, and Osborne, all of whom also figured largely in the annals of the County Medical Society.

Dr. Wright Post lectured and operated for over forty years, and Dr. Valentine Mott says he had no superior in all that time. He was distinguished for the clearness and accuracy of his teachings; he was always painstaking, and finally became peculiarly terse and apt in his instructions. His elocution, though plain and simple, was ready and natural; he never sacrificed accuracy to the graces and elegancies of diction.

Few professional men ever enjoyed a larger share of the public confidence and esteem. He was also remarkable for his great punctuality, and his deportment was uniformly considerate and more than usually correct; he was without major or minor vices; he was scrupulously pure and delicate; he was the friend and counsellor of young doctors; he was religious and strict in his attendance upon the Episcopal Church; he became a vestryman and finally senior warden of Trinity Church; he was a trustee of Columbia College and of the Historical and Philosophical Societies. He was for thirty-five years a surgeon and consulting surgeon of the New York Hospital, and for several years president and an active officer of the Medical Society of the County of New York; finally, he became President of the College of Physicians and Surgeons.

He had been the personal friend and correspondent of Percival Pott, Sir Astley Cooper, Charles Bell, and Drs. Fordyce, Home, Abernethy, Cline, and Blizzard.

He was greatly adverse to writing; and with the exception of a few papers descriptive of his most interesting surgical cases, he left no literary work behind him.

To sum up: As an anatomist he was accurate; as a surgeon, dexterous and bold; as a man, exemplary; as a leader and officer, masterly. He died in June, 1828, and his mantle and influence fell upon Alfred C. Post in 1829.

If I had not repeated the name of Dr. Wright Post again and again, even his best friends would have been easily misled into the belief that I was treating them to a biographical sketch of Dr. Alfred Charles Post.

I have only to substitute the Presbyterian for the Episcopal Church; to add the names of St. Luke's and the Presbyterian to that of the New York Hospital; the Medical Department of the University for that of Columbia College; and say that Alfred labored fifty-one years as a lecturer and operator and Wright only forty years, and the similitude, with the exception of a few minor personal differences, will be complete.

Then almost all that I have said in favor of Wright Post can be truly said of Alfred; and the biographical sketch of one may honestly be transferred to the other.

If we believed in the transmigration of souls we could say that Drs. Wright and Alfred Post were as one man, who had lived and worked well and gloriously for a full century. And we can add that this beautiful strain of honest, religious, and scientific men is continued in the son, Dr. George E. Post: he is a medical missionary in Syria; and at last the religious element of the Post family has overtopped, but not submerged, the surgical and medical.

Dr. Wright Post was more delicate and fragile as a

man, and is said to have been more elegant in his person, manners, and operations, than Dr. Alfred.

But Alfred was a well favored man. We will all long recollect his not large, but very well proportioned, sturdy, remarkably compact and squarely erect figure, with not an ounce of extra fat, or an inch of unusual height.

His head, face, and beard were strikingly like those which have come down to us in the portraits of Hippocrates. He was never absent-minded, but always seemed absorbed in reflection; still he was ever on the alert, hearing, seeing, and pondering everything, without any of that common and eager expression of strained attention which is so often noticed in less mature and less well-balanced men. His mouth was in repose decidedly firm, or almost hard, with a slight approach to grimness. But no one will forget the bright twinkle of his small gray eyes, or the genial smile which broke over him when he greeted his numerous friends, or took part in a discussion. In the latter his air was always that of one who was pleasantly, easily, and confidently assured of his mastery over the subject. If any one was tempted to challenge his memory or his knowledge he was generally brought to a standstill by timely quotations from published records, or by truthful reference to his own or others' experience. Then his smile quickly faded away and he again seemed in complete repose: thus he combined the stolidity and discretion of age with the enthusiasm and freshness of youth, and changed from one to the other at will. His command of language and of his temper was so great that it never seemed necessary for him to use angry or bitter words; but his replies at times were incisive, as keen as his knives, and as crushing as his lithoclasts.

No one ever heard him make an intentional misstatement, and few ever have known him to make a grossly incorrect statement; he was almost invariably accurate and always truthful. He never argued for the sake of argument, and yielded quickly as soon as convinced of any error, even if his opponent had been discourteous.

As a speaker and writer he was always clear, terse, logical, and impressive; as an operator he was always bold, but exceedingly careful, and as painstaking as he was self-reliant. He never sacrificed safety to speed. He often seemed dry and hard, but the choicest treasures of literature and poetry always seemed at his instant command, and his charity for all never failed him.

Next to his religion and surgery Dr. Post was an earnest temperance man, and a great example of the benefits of total abstinence from alcohol and tobacco. He had no

> Mellow casks of gentle wine
> Of equal age with mine.

But only

> A surgeon's beverage, pure and cheap,
> Should e'en Mæcenas be my guest.
> No rich vintage of the luscious grape,
> But only sober cups shall crown my feast

He was also extremely frugal and could honestly say,

> Nor ask I more than sense and health
> Still to enjoy my modest wealth;
> From age and all its weakness free,
> O Son of God, preserved by Thee.]

We have seen that Dr. Post had many more than the usual advantages of medical men. He was the son of an eminent and prosperous merchant, Joel Post; his primary and classical education were more than good; his professional education was excellent, both here and broad.

He was led on by Wright Post and the New York Hospital; he had many friends and early patrons; he always had an abundant field for exertion; he had a vigorous constitution; he was never a "medical orphan," which in olden times was defined, "as one who had no uncle in the New York hospitals;" he had all the opportunities and abilities which go to make a great surgeon and an accomplished man, and used them unceasingly.

We can all agree that the example which he has set, of a man who lived a thoroughly earnest, unselfish, Christian, and most useful life, cannot fail to leave an excellent influence which will last long after this tireless worker himself has gone

His end was finally quick and peaceful, in the fulness of time; and no one can say, "If he had died earlier his reputation would have been greater." We can imagine his last message to us to be:

> My friends, the funeral sorrow spare,
> The plaintive song and bitter tear,
> Nor let the voice of grief profane
> With loud laments my happy home.

Progress of Medical Science.

Nephrotomy for Total Suppression of Urine.—Mr. Clement Lucas performed this operation in Guy's Hospital on October 29th (*The British Medical Journal*). A woman, from whom he had removed the right kidney for total destruction of its secreting structure by large calculi and hydronephrosis about four months ago, and who had made a rapid and complete recovery, was suddenly seized with great pain in the left kidney, followed by vomiting, headache, and suppression of urine. She passed urine last on Sunday morning, October 25th, between eight and nine o'clock; and from that time till the operation, on Thursday afternoon, no urine passed and vomiting was persistent. Her medical attendant, correctly interpreting the meaning of her symptoms, placed himself in communication with Mr. Lucas, and the patient was brought to London on Wednesday, October 28th. It was thought that the effect of diuretics in flushing the kidney might yet be tried while the patient was watched. These proved of no avail, and on Thursday afternoon, the patient having become drowsy and much weaker, Mr. Lucas cut down on the remaining kidney, and removed from the pelvis a conical calculus, measuring seven-eighths of an inch by one-half in its greater diameters. Total suppression had then lasted one hundred and two hours. A free flow of urine took place at once through the wound, and the patient was relieved of her vomiting and drowsiness. Five days after the operation she was doing well and feeling comfortable.

Herpes Tonsurans and Favus.—In some stages it is very difficult to distinguish between herpes tonsurans and favus. Dr. G. Behrend, of Berlin, has recently discovered a method which enables one at once to recognize which of the two diseases is before him. Behrend employed the reaction, observed by him and by Duckworth, which chloroform produces on hair attacked by trichophyton, the fungus causing herpes tonsurans. Whenever such hair is moistened with chloroform it shows, after the evaporation of the drug, which occurs within from two to three minutes, a perfectly white color, while normal hair experiences under its influence no alteration of color whatever. This change of color in the diseased hair proceeds only so far as the fungus had penetrated. The cause of this color-change is to be looked for in the splitting of the hair, and in the entrance of air through the clefts in consequence of this splitting. Though the hair is also split in favus, this never happens to such a high degree, and the chloroform reaction has no influence at all on favus. The same test cannot be used to determine the beginning of a cure, as the change of color cannot be so easily observed while the hair is in situ on account of the clear skin; but if a few hairs are extracted, and then subjected to the action of the chloroform, the same alteration of color will at once be observed, if the fungus is still present, while no such change will occur if the trichophyton has been destroyed.—*Centralblatt fur Chirurgie.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE RELAPSES OF TYPHOID FEVER.

THE subject of the relapses of typhoid fever has hardly received the attention it deserves from American writers. We take occasion, therefore, to present some facts regarding it, collected in part by Dr. R. Longet, and published in *L'Union Médicale.*

The frequency of relapses in typhoid fever is very variable. Among German and Swiss observers we find the following statistics given, showing the percentage of relapses: Liebermeister, at Basle, 7.4 before using baths, 9.8 after; Ziemssen, at Munich, 13; Pfeurer, at Munich in 1856, 3; Gerhardt, at Würzburg, 6.3; Griesinger, at Zurich, 6; Griesinger, at Leipsic, 8; Immermann, at Basle, 15 to 19; Henoch, at Berlin, 16.6; Nothnagel, 30. In France: Jaccoud, at Paris, 9; Daga, at Nancy, 7.7. In England and Scotland: Murchison, in London, 3; Maclagan, in Dundee, 10. Schroeder, in St. Petersburg, 2.5.

In this country we are not aware that any extensive collection of statistics regarding relapses has been made. The belief is common that such accidents are rare. Dr. James H. Hutchinson met with 5 relapses in 80 cases, which makes a percentage of 6.25.

Very few physicians have ever seen double or triple relapses of typhoid. Ziemssen states that among 2,140 he met with 4 cases in which the relapses occurred twice. Bucquoy and Ziemssen claim to have seen the typhoid relapse occur a third time.

Typhoid relapses rarely if ever occur in patients who have reached the age of forty, according to Steinthal; and, as a rule, the patients have not passed the age of thirty-two. Sex does not seem to have any influence on the tendency to relapse.

Nearly all authorities are agreed that in at least three-fourths of the patients who have relapses the primary attack is of a mild type. This may be accepted as an established fact.

The duration of the relapse is, in the majority of cases, shorter than that of the original attack. This was true in about four-fifths of the cases reported by Jaccoud, Schroeder, and Steinthal.

The question arises whether there is anything in the character of the primary attack, or in the symptoms after its decline, to indicate that a relapse may occur. Numerous indications and means of prognostication have been suggested, but of them all only one, we believe, deserves any confidence, viz.: the continued enlargement of the spleen after the close of the primary attack and during the interval of apyrexia. This should make it imperative for the physician to map out and mark the boundaries of the spleen, and to watch any changes in its size. The application of Ehrlich's diazor-benzole test will be a help in telling the nature of the pyrexia.

The duration of the apyretic interval ranges from one to forty-six days, but in nine-tenths of the cases the relapse occurs before the fifteenth day. If that day is reached without fever, the danger of relapse is practically passed.

The relapses occur either sharply, with perhaps a chill, or gradually, with an ascending febrile curve like that of the primary attack. The two types are about equally divided as to frequency. It appears, however, that when the relapse comes on briskly, its duration is likely to be shorter. Steinthal believes that if the patient have a dicrotic pulse during the first attack, and it be also marked in the relapse, the prognosis is bad.

The pathognomonic sign of the fever, *i.e.*, the roseola, is observed in from one-fourth (Jaccoud) to one-half (Steinthal), or even three-fourths (Ziemssen), of the cases. The eruption appears early; perhaps, on the average, about the fifth day, although it may be earlier or later.

The general character of the relapses, as is well known, is as a rule mild. Severe cases are very exceptional. The mortality in relapses was with Ziemssen 2.8 per cent.; with Schroeder, of St. Petersburg, 5.5 per cent.; with Steinthal, 8.8 per cent.

None of Hutchinson's 5 cases died. On the other hand, Murchison had a mortality of 7 among 53 cases, or nearly 14 per cent.; and Ebstein lost 3 out of 13 cases, or about 24 per cent.

The diagnosis of a relapse is not always made without difficulty, and no doubt mistakes have often occurred. A number of French writers have described pyrexial attacks occurring after typhoid, lasting one or two weeks, and having none of the symptoms of typhoid fever. Bernheim calls it a fever of convalescence, and ascribes it to "a habit of the nervous system." There is no doubt that mild septic or malarial fevers may follow typhoid and excite alarm. Of the nature of the second attack there is no uncertainty. It is a genuine typhoid fever, and in fatal cases a second set of intestinal ulcers is found.

The attempts to explain the pathology of the second attack have excited many discussions. It is most probable that there is simply a reinfection.

The practical question, whether a relapse can be prevented, seems to have excited very little interest as yet. We learn of no measures which are systematically recommended for an accident that occurs, on an average, in seven out of every hundred cases. It appears to be shown that active hydrotherapeutics tends to increase the per cent. of the relapses. A careful attention to the patient's discharges, to securing a plentiful supply of fresh air, and to the diet, is to be observed. The use of naphtholin, as recommended by Rossbach, disinfects the bowels, and may very likely be of advantage.

HEREDITARY SYPHILIS.

MR. HUTCHINSON, of London, in his third and final Lettsomian lecture, took up the vexed subject of hereditary syphilis, and discussed it in his usual clear and con-

vincing style. Almost all our knowledge on this point is of comparatively recent acquisition. It was not very long since it was held that the mother could convey syphilis to her child only by contagion at the time of parturition; and even when intra-uterine infection was admitted, there was still great scepticism as to whether the father could transmit the disease. As regards the whole subject of hereditary syphilis, the evidence is almost always circumstantial, and that which leads us to believe that a father could transmit syphilis independently of the mother is peculiarly of this kind. In any given case it is next to impossible to prove that the mother had never suffered. When, however, we find the history repeated hundreds of times, that a man known to have had syphilis marries a woman apparently healthy and believed to have been chaste, and a syphilitic child is produced without any obvious illness in the mother, we are forced to believe that inheritance from the father is not only possible, but common.

Exactly the same kind of proof was offered by Mr. Hutchinson in respect to the influence of an infected fœtus upon a previously healthy mother. He referred to a series of cases he had published many years ago, which illustrated the assertion of Ramsbotham, Harvey, and others, that the fœtus might infect its mother. The fallacy in all these cases is the obvious one that the mother might have had syphilis herself. There is, however, a limit to the acceptance of that explanation. Proof is wanted of two things: (1) That a woman may carry a syphilitic child without herself suffering in any obvious manner; (2) that she does really receive a taint, although showing no symptoms. Of the first the proof is abundant. That of the second is, perhaps, less convincing. It consists in the facts: (1) That women often present tertiary symptoms who have never had primary or secondary ones; and (2) that they are not susceptible to infection by their infants. Mr. Hutchinson said he had adduced many instances of the former; and, as regarded the latter, he certainly thought that Colles' law (that a sucking infant cannot infect the nipple of its own mother) stood the test of time. He had never seen an exception to it. He had seen cases in which women contracted chancres on the nipple from the mouths of infants they had suckled, but in no case was the infant which conveyed the infection the offspring of the woman who acquired the chancre.

About two years ago he had met with an apparent exception to Colles' law. A mother who was suckling her infant had a chancre on her nipple, and her child also showed symptoms of syphilis. On careful inquiry, however, the child was found to be the subject of primary acquired syphilis, and not of inherited taint.

Is it possible for a mother who acquired syphilis during her pregnancy to infect her fœtus? Mr. Hutchinson said that, as a matter of inference, he should be inclined to reply that, if sufficient time were allowed, she must almost necessarily do so. He had himself met with several cases which appeared to be very conclusive as proof of its occurrence, one of which he narrated.

Respecting the influence of inheritance from one or the other parent, Mr. Hutchinson said his conviction was that it made no difference. The inheritance was as certain or uncertain in one case as in the other, and he had not been able to trace any difference in the severity. Nor did he believe that the fact of both parents having suffered made any difference in the severity of the disease in the child, though it made the occurrence of the disease more certain. He then went on to discuss those cases in which syphilis was transmitted to several children in succession. He combated the generally received notion that the elder children always suffer most, though he admitted that interstitial keratitis is met with in first-born children in very disproportionate excess. His own belief was that there was no reason for thinking that the transmission of syphilis was ever a matter of degree, but rather that, if a child inherited any taint, it inherited the whole malady.

It is an interesting speculation whether the sex of the infant influences its liability to suffer. The speaker said he had endeavored in vain to find any law in respect to difference of severity of inherited syphilis in the two sexes. He remarked, however, that it was established by statistics that a majority of those who suffered from iritis in infancy, and from keratitis when adolescent, were girls.

As this whole subject is one which Mr. Hutchinson has made peculiarly his own, his opinions are necessarily regarded by every one with great respect, even when they cannot be accepted without qualification, and they are certain to excite interest and to furnish abundant food for thought.

NEW HYPNOTICS.

THE chemical and pharmacological laboratories of Germany are competing with the flora of California for the honor of getting out the most new remedies. The latest contribution is an ethyl-ether, first used by Schmiedeberg. It is called urethran; it has the formula $NH_2 CO_2C_2H_5$, and is an ethyl-ether of carbonic acid. It occurs as a white crystalline body, easily soluble in water, and having a not unpleasant taste and no odor. The narcotic properties of urethran were first noted by Schmiedeberg on animals, and by Jolly on men. Dr. Kobert, of Strassburg, suggested its possible value as a hypnotic to Dr. R. v. Jaksch, of Vienna, the physician who first introduced thallin to the notice of the profession. It seems not unlikely that in urethran Dr. Jaksch has given us a drug of some value. To him, at least, belongs the credit of first thoroughly testing it. This he did first upon animals, and then upon twenty patients, making in all one hundred and ten separate tests. His experiments upon rabbits showed that, even in doses of seven grains to the kilogramme of body-weight, no toxic effects were produced. Jaksch began by administering the medicine in doses of four grains. This produced no result. He then gave it in half-gramme doses, with feeble hypnotic effect. The dose was then increased to one gramme (fifteen grains), and found to act with certainty and satisfaction. Urethran appears to act like chloral upon the brain, but it is a milder hypnotic. It does not affect the peripheral sensory apparatus, and therefore does not relieve directly cough or neuralgic pains. Jaksch concludes that urethran is very well borne by patients, causing no nausea, and having absolutely no disagreeable after-effects. The sleep which it produces is a natural one. The drug is without danger, and for this reason

he thinks it will be found very useful in children's troubles.

Hypnone, or methyl-phenyl-acetone, is a substance introduced into therapeutics by Drs. Dujardin-Beaumetz and Bartet. It is a liquid which crystallizes below the ordinary temperature in beautiful white needles, boiling at a temperature of 198° C. It has an odor resembling somewhat both that of the bitter almond and the orange-blossom. This odor renders the capsule of gelatine the most acceptable form of its administration. Popof and Neacke have shown that it is transformed in the system into carbonic and benzoic acids, and have detected its final transformation in the urine as hippuric acid. In the adult a dose of from five to fifteen centigrammes (gtt. i.–x.) produces sound sleep.

In order to obtain a well-marked hypnotic effect, the quantity proportioned to the age and temperament of the patient should be administered in a single dose. One of the inconveniences attending its use is that it communicates a disagreeable odor to the breath, being eliminated, like most volatile bodies, through the respiratory organs. M. Limousin recommends that it should be administered in doses of two drops mixed with a few drops of almond-oil in gelatine capsules. M. Vigier has given the following form for a syrup: Hypnone, one drop; alcohol (60°), one gramme; syrup of orange-flowers, six grammes. Of this mixture a teaspoonful corresponds to one drop.

Reports appear to show that the hypnotic effect of hypnone is not great, and that it is only of service in certain forms of nervous or alcoholic insomnia.

THE LAPAROTOMY EPIDEMIC.

The *Medical Press and Circular* has aroused considerable discussion over the subject of the prevalent fondness, in certain hospitals, for performing laparotomy for the removal of the uterine appendages and other purposes. Comment was first caused by publishing a statement of Dr. F. Durlach, who said:

"Every Monday, at 2 o'clock, I see out-patients at the Hospital for Women. If, unable to attend, I were to tell the nurse to send into hospital those women who suffered most and had been longest ill, out of ten sent in, seven or eight would have some chronic inflammatory disease of the uterine appendages, and most of them would prove to be incurable without surgical treatment."

This, it was thought, was as much as to say that over half of chronic uterine cases need to be spayed.

The *Press* says that a crowded meeting of the members of the Liverpool Medical Institution was held on the 4th ult. to discuss this subject. The result of the discussion was that a resolution bearing on the subject was proposed by Dr. Grimsdale, and carried unanimously: "That in view of the large and increasing number of cases of abdominal section in the Hospital for Women in this city, as shown in their Annual Medical Reports for the years 1884 and 1885, this meeting is of opinion that a select committee be appointed for the purpose of investigating the grave questions of practice and ethics involved in the performance of these operations."

Whatever be the merits of the particular controversy stirred up in England, it is beyond question that laparotomy is now being performed with extraordinary, and probably unnecessary, frequency both in Europe and this country.

Every young gynecologist is ambitious to remove the tubes or the uterus, or at least an ovarian cyst; the older ones are equally anxious to remove a hundred.

It is not borne in mind, as it should be, that it is a most serious thing, morally, to unsex a woman, and that it is still a most dangerous thing to open the abdominal cavity. The small percentage of mortality attained by such men as Keith, Tait, and Schede is the result, in part, of an extraordinary manual dexterity which few possess naturally, and fewer still ever can get the opportunity to acquire. There are very few men who really understand even the technique by which the operation is made so free from danger. The mortality from the laparotomies of most American and English surgeons is comparatively high, and serious harm has, we fear, been done by the wide heralding of the extraordinary success of a few adepts.

CALOMEL REDIVIVUS.

We hear, in a somewhat regular periodicity, of the old Kentucky doctor who said (usually on his death-bed) that there were only four medicines in the Pharmacopœia, all the rest helped the druggist but hurt the patient. These medicines were opium, quinine, a purgative, and calomel. The last-named drug has been greatly abused, but there is no doubt that it deserves its position in the medical tetrarchy above mentioned, and in the last decade it has been used more and more extensively. We have occasionally discussed its alleged virtues in "sedative" doses in diphtheria and pneumonia. We cite below some recent recommendations of its use in various other fields:

Dr. Jendrássic has found, in cases of cardiac dropsy, that calomel in appropriate doses causes well-marked diuresis, a "sort of diabetes insipidus," by which the results of want of cardiac compensation, dropsy and œdema, are dissipated. The effect comes on within twenty-four hours; one and a half grain of the drug being given three to five times a day. No diarrhœa is usually produced; but, in some cases, it had to be prevented by the administration of laudanum. Salivation and stomatitis were obviated by the prescription of a chlorate of potash gargle from the first. The result, in all cases in which the treatment was adopted, was beneficial, no unfavorable depressing symptoms being noticed.

Professor Sacharjin has recently recommended the employment of calomel in a number of disorders beginning with affections of the bile-ducts and hypertrophic cirrhosis of the liver. "Those cases," he says, "are especially suited for calomel treatment that present as marked features constant pain in the hepatic region and fever. The calomel should be given in doses of one grain, at hourly intervals, until six doses are taken. Thereupon the powder may be administered every two hours. Not more than twelve successive doses should be given. Thus no diarrhœa of any serious consequence happens. It is advisable to attend strictly to cleansing the teeth at frequent intervals, and chlorate of potash is suggested as a mouth-wash."

Calomel used as above is recommended in erysipelas

occurring in elderly persons with a tendency to heart-failure. Also in the first week of typhoid fever if no diarrhœa exists.

In acute lobar pneumonia digitalis, quinine, salicylate of soda, and cold water do not accomplish as much as calomel, which we are told should be administered early.

Acute Bright's disease is another condition that Sacharjin has treated with calomel, with the result of reducing the fever, relieving pain, and rendering the urine less albuminous. Profuse diarrhœa and great feebleness are to be considered as contra-indications.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE latest authentic accounts pronounce matters all quiet since the election of delegates from the Philadelphia County Medical Society to the American Medical Association. We are informed that the action taken at that time represents the sentiment of the great majority of the best physicians of Philadelphia, and that those who have talked most about "packed meetings" have not moral or numerical strength enough to venture on a protest.

THE QUESTION OF VAGINAL INJECTIONS.

IT would be highly interesting to learn how many of the women who go away from the doctor's office with orders to use hot vaginal injections carry out the orders, and also how many carry them out properly. The percentage of conscientious and skilful injectresses, if we may be allowed the word, is certainly extremely small. This is partly due, no doubt, to the somewhat elaborate and unpleasant gymnastic performances that, we are told, are necessary for carrying out efficiently the hot-water treatment.

Rubber cloths, or patent pans, syringes, buckets, chairs, boiling water, and medicating powders are the necessary factors in the treatment, and the collection and symphonic arrangement of these particulars form a considerable task to the head of a household. If women do not absolutely dislike these hot-water calisthenics, they certainly are not fond of them, and give up the practice on the slightest excuse. Whether it is the general complexity or the ungraceful horizontalness of the process which is most repugnant to woman, we are not prepared to say.

In a recent communication in the *Journal of the American Medical Association*, Dr. W. Thornton Parker seems to think that it is the posture which most modest women object to. And he comes to their relief with the statement that an injection given in the sitting position may be just as efficient. He recommends that the woman use the bidet, which is "a triangular stool about sixteen inches high, containing a porcelain basin. This is filled with hot water, and the patient, sitting astride of it (the bidet), injects the fluid with a Higginson, English, or Parker modified syringe.

The *Weekly Medical Review* comments somewhat sarcastically upon Dr. Parker's plan, and defends the old method. No doubt this latter is better when properly and thoroughly applied, but we are inclined to think that women will take more kindly to the simpler and more æsthetic process suggested by Dr. Parker. And in most cases the bidet method, systematically used, is better than an irregular and spasmodic indulgence in the conventional saturnalia of buckets, blankets, pans, stools, and so forth.

SPECIALLY TRAINED MEDICAL MISSIONARIES.

IT is announced that "to train young men in the practice of medicine and surgery, so as to fit them for work in China, India, or Africa as medical missionaries, the New York Medical Missionary Society requires, during the present year, $5,000." Of this amount $1,400 has already been subscribed, Mr. Cornelius Vanderbilt contributing $600 and his brother, George, $300. Five other gentlemen have contributed $100 each. In order to assist in raising the balance, a meeting was held at the Broadway Tabernacle during the past week, at which the matter was presented and appeals for help made. Fifty applicants desire to be educated as medical missionaries, but the society can only pay for nine. With such a surplus of young graduates in medicine as is furnished every spring, we confess that we are at a loss to see the need of special funds for specially educating medical missionaries. Of the four thousand annual graduates in medicine, we only need two thousand. All the rest might very well be employed in disseminating the gospel in foreign parts.

ADVICE TO HARVARD STUDENTS.

PROFESSOR T. R. EDES JACKSON gave one of a series of lectures on the professions to the students of Harvard College this week. He presented the subject of success in the medical profession.

"One great drawback to the profession," he said, "lies in the fact that the law offers it no protection, as it does in other countries. It is a curious fact that, in the United States a certificate of insanity is the only thing which requires an education of a physician; in nothing else does the law interfere. The consequence is that the country is overrun with people who call themselves physicians, but who are such only in name. This state of things, instead of turning educated men away, ought to bring them to the profession. By this means can the line be drawn deep and wide between the real and the sham physicians. What is needed most is men of learning and practical knowledge to elevate the profession in the eyes of the public."

Professor Jackson does not seem to have described the opportunities offered by the medical profession to educated men in strong enough light. We believe that there is no better opening than medicine for thoroughly educated young men, who have any kind of aptitude for getting along.

Professor Jackson is mistaken also in saying that medicine necessarily requires an entire and exclusive devotion beyond that demanded by other pursuits. This is an old commencement oration myth, and it is time it were laid on the shelf.

M. PASTEUR'S SUCCESS.

M. PASTEUR has announced to the Académie des Sciences that his inoculation-method against rabies has been successful in 325 cases. The 325 cases include, we presume, the Newark children, who were not bitten by mad dogs at all, and probably a number of other perfectly

healthy people. One must take from the 325 also the seventy-five per cent. of people who, although bitten by mad dogs, yet never get rabies; and finally, we must take out those in whom there has not yet been time—now only about four months at the furthest—for the disease to develop. With these necessary depletions, Pasteur's figures become of very insignificant proportions.

News of the Week.

The Health of Working Women.—According to the Commission on Labor Statistics for the State of New York, the health of working women is in the main fairly good—as good, perhaps, as the health of women generally. Working women are rarely subject to the diseases resulting from injurious trades like those of painting, working in mercury, etc. As a rule, work in factories is more healthful than work in houses.

M. J. B. Baillière, who recently died at the venerable age of eighty-eight, was the leading medical book-publisher of Europe for many years. The numerous eulogistic notices and addresses which appeared after his death have been collected into a memorial volume, a copy of which has reached us. It forms an eloquent record of a well-spent life.

Free Burial is granted in all cities to the paupers, but the mortuary rites are so extremely simple, and the funeral supplies so painfully meagre (being limited to a pine box and a contract shroud), that no one who can possibly raise enough money for the undertaker will allow a relative, friend, or acquaintance to be buried at public expense. Undertakers' charges are, however, often a serious tax on the poor. We recall a case in which a patient died of acute phthisis, the disease lasting about two months. The doctor's bill was $33, the undertaker's, $125. The city of Basle, Switzerland, has recently passed a law providing free burial to all its residents. The State provides the grave, coffin, pall, hearse, and sufficient employés for attendance at the funeral.

The International Medical Congress.—The prevailing feeling here regarding the Congress now is one of profound apathy and indifference. The news from abroad is equally discouraging. Almost the only smiling face is published at Chicago weekly. We hope for better news after the St. Louis meeting.

Billroth and Esmarch on the Study of Latin and Greek for Those Intending to Study Medicine.—Professor Billroth has written a letter upon the above subject to Herr V. Pirquet. Billroth states that he entirely agrees with the already expressed views of Professor Esmarch, viz., "that medical language is so filled with Latin and Greek words that some knowledge of those languages is absolutely necessary for medical students; and nothing shows the parvenu more plainly than his use of foreign words of which he does not understand the meaning. Although Latin and Greek are no longer international languages of the learned, they help to make scientific men of different nationalities understand each other, and to-day all new scientific terminology is still formed from the Greek." Billroth thinks that it would be sufficient for the student to study Latin and Greek grammar, and read, in Latin, Cæsar, some of Cicero, Ovid, and Virgil; in Greek, Xenophon and Homer. Professor Esmarch's views coincide with those of Billroth.

Pasteurization for the Prevention of Diphtheria.—The news is cabled from Paris that M. Pasteur believes that he can prevent or cure diphtheria by a process of inoculation.

John Hunter's House under the Hammer.—On February 16th and 17th the old house at Kensington once occupied by John Hunter was sold at auction. Among the articles advertised for sale was "the historical copper, coving and fittings, used for the purpose of boiling the remains of the Irish giant, Byrne O'Brian."

The Association of Physicians and Pathologists.—A national association under the above name is in process of organization. Two preliminary meetings have already been held in this city, at which it was decided that the association should be organized with a membership limited to one hundred; that it should hold an annual meeting at Washington in June, and that the first meeting should he held in that city June 16th and 17th in 1886, under the presidency of Dr. Francis Delafield.

A Sarcomatous Tumor Made to Disappear by an Attack of Erysipelas.—A girl, aged eight, had a sarcomatous tumor larger than a hen's egg, involving first the left tonsil, and later nearly the whole posterior half of the buccal cavity. Tracheotomy had to be performed. The patient then caught erysipelas from another patient, the disease lasting six days. At the end of this time the tumor was reduced to two nodules, the size of a pea, which were excised. Two months later, says Dr. D. Biedert, who reports the case, the disease had not returned.

Cocainization by the Cataphoric Action of the Electric Current.—At a recent meeting of the Royal Society of Physicians of Vienna, Wagner announced that by saturating the positive pole of the galvanic battery with cocaine, and placing the two poles on the surface of the body near each other, the cocaine is carried into the tissues, producing inter-polar anæsthetization. This has been tried by several physicians in this city some time ago, but with no results of practical value.

The Next Meeting of the American Medical Association.—The organization of the next meeting of the American Medical Association, to be held in St. Louis, Mo., on May 4th, 5th, 6th and 7th, is announced as follows: Practice of Medicine, Materia Medica, and Physiology: Dr. J. T. Whittaker, Cincinnati, O., Chairman; Dr. B. L. Coleman, Lexington, Ky., Secretary. Obstetrics and Diseases of Women and Children: Dr. S. C. Gordon, Portland, Me., Chairman; Dr. J. F. Y. Paine, Galveston, Tex., Secretary. Surgery and Anatomy: Dr. Nicholas Senn, Milwaukee, Wis., Chairman; Dr. H. H. Mudd, St. Louis, Mo., Secretary. State Medicine: Dr. John H. Rauch, Springfield, Ill., Chairman; Dr. F. E. Daniel, Austin, Tex., Secretary. Ophthalmology, Otology, Laryngology: Dr. Eugene Smith, Detroit, Mich., Chairman; Dr. J. F. Fulton, St. Paul, Minn., Secretary. Diseases of Children: Dr. W. D. Haggard, Nashville, Tenn., Chairman; Dr. W. B. Lawrence, Batesville, Ark.

Secretary. Oral and Dental Surgery: Dr. John S. Marshall, Chicago, Ill., Chairman; Dr. A. E. Baldwin, Chicago, Ill., Secretary. "A member desiring to read a paper before a Section should forward the paper, or its *title* and *length* (not to exceed twenty minutes in reading), to the Chairman of the Committee of Arrangements, at least one month before the meeting."—*By-Laws.* Committee of Arrangements: Dr. Legrand Atwood, St. Louis, Mo., Chairman.

Amusing the Insane.—Praiseworthy efforts are being made at the Hudson River State Hospital for the insane to carry out the modern idea of keeping the insane patients occupied and amused. Statistics show that a very large majority are kept employed more or less of the time in work or amusement. One of the novel features is the establishment of a day-school which about sixty men and forty women attend. The efforts to secure musical entertainment have their humorous side. Dr. Atwood, one of the Assistant Physicians, in his report, says: "An attempt was made to organize a band, or orchestra, and six meetings of all patients and attendants possessing any musical ability were held in the amusement hall for rehearsal. The leader of the proposed band, however, having by this time run away, and the B flat cornet becoming unusually disturbed, the drum and bass-horn were considered scarcely adequate in themselves to please the public, and the idea was postponed until our corps of employés is increased, and we have our accommodations for the chronic insane."

The Pathological Future of the Negro.—The Florida *Medical and Surgical Journal* draws a graphic but gloomy picture of the negro of to-day, and predicts for him physical decay and moral ruin. It is intimated, also, that the Southern doctors do not take so much interest in the negro's condition, since "the rattle of the planter's shekels" is no longer behind him. Some hopes of improvement are expected from the educated negro doctors, who have already done good work among their fellows. We share in these hopes, and, with all respect to the cloth, think that if one-half the colored clergymen were asphyxiated and their places taken by intelligent medical men, the negro's condition would be vastly improved. The negro is not dying out, however, for though the death-rate is enormous in cities, it is more than balanced by the high birth-rate and low death-rate in the country.

A Pernicious Anæmia may be caused by the presence in the intestine of the parasite *ankylostonum duodenale*. This fact, first discovered by Perroncito and Corseoli among the workmen in the St. Gothard Tunnel, has been confirmed by later observers. Recently Dr. Edwin Snyers, in the *Progrès Medicale*, reports several cases occurring among workmen in a brick-yard near Cologne.

Cremate—Cremation—Cremationist—Crematorium; these are the new words introduced by a new journal called *The Modern Crematist*, published at Lancaster, Pa., and devoted to cremation. It includes, under a sub-title, "Cremation Gossip." A dealer advertises "cinerary urns," and a crematorium company announces its constant readiness to receive and incinerate bodies. If friends accompany the body, they are advised to "buy a regular ticket, and check casket as baggage." The knowledge that mourning children can check their parents as baggage, and get a trip to Pennsylvania at practically reduced rates, is of interest, and shows that cremation has passed the sentimental stage, and got upon a solid commercial basis.

Railway Hospitals for Injured Employees.—Most railroads do not attempt to care for injured employees. We learn from Dr. F. R. Lewis, in the *Kansas City Medical Index*, that the Wabash, St. Louis, and Pacific Railway Company have established a surgical service for the benefit of their employees. These latter have to pay a small percentage of their wages to form a hospital fund. With this two hospitals are supported, one at Springfield, Ill., and one at Kansas City.

A Plea for the Madstone.—A Washington physician writes to the Washington *Post* a plea for the madstone. The physician in question states that he feels a debt of personal gratitude toward the mystic mineral because his grandmother was cured of rabies by it when a girl. This, no doubt, gives a little bias to the correspondent's opinions. He says that he has witnessed the application of the madstone to wounds caused by the bite of a rabid dog. The adhesion of the stone was so strong that it remained *in situ* even when the wound was turned down. Well! folly dies hard.

A New Neurological Journal has appeared in Chicago. It is called the *Neurological Review*, and is edited by Dr. J. S. Jewell, who established, and for some years edited, the *Journal of Nervous and Mental Diseases.*

Medical Advertising in the Daily Papers.—Another flagrant instance of medical advertising in the daily papers has appeared in Auburn, N. Y. The operation described was the common and simple one of wiring the bones in a case of reunited fracture, but it was heralded as "a remarkable surgical operation" which "for nerve and nicety has hardly been equalled." The young seeker after notoriety who procured this notice is doing things "unworthy of a physician and a gentleman."

The Mad Dogs of Newark.—The dog that bit the Newark children who were sent to Paris to be inoculated by Pasteur also bit seven dogs, which have been kept in seclusion ever since. On March 2d the dogs were released, none of them having developed rabies. The probability is very great, therefore, that the dog which bit the Newark children was not rabid, and, consequently, that the excitement aroused over the subject of hydrophobia in that city was uncalled for.

Rush Medical College held its Forty-third Annual Commencement on February 16th, and graduated a class of one hundred and fifty-six.

Dr. N. S. Davis.—We are sincerely glad to learn that Dr. Davis has, in a great measure, recovered from his attack of hemiplegia.

All Preparations of Morphine lawfully sold in the State of Georgia must be wrapped in a scarlet paper, and marked with a scarlet label naming the contents of the package in white letters.

Does it do any Good to Support the Perineum during Labor?—A correspondent writes, citing the statement made that perineal lacerations are very rare in the Vienna Hospital, and asking whether there is any demonstrative evidence that supporting the perineum does any good in ordinary cases of labor. Judging by the frequency of perineal lacerations either support does no good, or the practice of supporting the perineum is not very prevalent.

There is not a hospital in London which is not expending more each year than it receives. So says *The Hospital Gazette.*

American Veterinary College.—The Eleventh Annual Commencement of this institution was held at Chickering Hall on Monday, March 1st, before a large audience of the friends of the college. Twenty-eight graduates received the degree of Doctor of Veterinary Surgery.

A Statue to Claude Bernard has been erected in the garden in front of the College of France, and was unveiled on February 7th. Addresses were delivered by M. Paul Bert, Professor Chauveau, and M. Dastre.

Homœopathists Seeking Representation on the Staff of the Massachusetts General Hospital.—The *Boston Medical and Surgical Journal* says: "The trustees of the Boston City Hospital gave a hearing Friday evening, February 19th, to the remonstrants against the petition that homœopathy should take part in the medical and surgical treatment of patients at the hospital. Members of the hospital staff were present by special invitation of the trustees."

The Death of Dr. Wm. Wetzel, of this city, is announced. Dr. Wetzel was a graduate of Carlsruhe, in 1846, but had practised medicine in this country for many years.

What Should be Done at the St. Louis Meeting of the American Medical Association.—The Kansas *City Medical Index* says: "The St. Louis meeting will do the profession no credit, unless the wiser and more considerate members from both factions get together and frame a compromise to be submitted without debate. By some such mode of settlement as this the Congress may have an eminently creditable meeting in the end. In order to save the American profession from disrepute, harmony must be restored at the St. Louis Association meeting. Concessions should be made by both factions, and the whole matter quietly settled by a fairly constituted council."

The Nashville *Journal of Medicine and Surgery* says: "The topic of the International Medical Congress will be the absorbing question for discussion, and will, we hope, be definitely settled, at least so far as it relates to the Association. Of late years this Association has appeared to degenerate into a body merely medico-political, and it is time something were done to elevate it to a proper standard and make it what the British Medical Association is to the profession in England—representative and national. Political intrigue and trickery have too long held sway in this Association, and it is time the profession saw to it that it be no longer thus degraded, and be brought back to the place it occupied in its palmiest days. We hope, therefore, that all who can will make an effort to attend the coming meeting.

The Late Dr. Alfred C. Post.—At a special meeting of the Medical Board of St. Luke's Hospital, held February 20, 1886, the following was unanimously adopted:

Whereas, It having pleased God to remove from our ranks our beloved associate, Dr. Alfred C. Post, who was from the first organization of the medical staff till his death—a period of twenty-seven years—one of the consulting surgeons of St. Luke's Hospital, we desire to record our appreciation of our loss.

Dr. Post was the oldest member of our board. Up to within a few days of his death he was a constant attendant and much valued adviser at all important operations. His vast experience, his extensive knowledge on all topics connected with our professional work, his sound judgment, and his readiness to assist others, make his loss to our hospital staff almost irreparable. He brought to our councils the surgical knowledge of a former generation, and complete information with regard to the results of the most recent scientific investigations. Dr. Post's whole life, moreover, social as well as professional, bore the impress of a rarely honorable and Christian character. His loss will be deeply felt by the entire community, in which he spent a long and eminently useful life. We desire, also, to tender to the members of his family our deep sympathy with them in their affliction.

Robert Abbe, M.D.,
Charles McBurney, M.D.,
A. B. Ball, M.D.,
For the Medical Board.

Reviews and Notices.

A Guide to Sanitary House-Inspection; or, Hints and Helps Regarding the Choice of a Healthful Home in City or Country. By William Paul Gerhard, C.E., Consulting Sanitary Engineer; Author of "House-Drainage and Sanitary Plumbing," "Hints on the Drainage and Sewerage of Dwellings," and "Diagram for Sewer Calculations." New York: John Wiley & Sons. 1885.

The family physician is very often consulted by his patients as to the healthfulness of their dwellings, or is led to inquire into the sanitary conditions of a house by reason of the occurrence of disease among several members of the same family. And it is safe to say that he is frequently no better qualified to pass judgment upon these matters than is the householder himself. In such a predicament this little book will prove very useful to him, by pointing out the most common defects and enabling him to detect them if present. It contains just enough to give one an intelligent idea of the essentials of house-inspection without wearying the reader with minute details. And not only the physician, but every one who cares for the health of himself or his family, will find this practical little work of service.

Alpine Winter in its Medical Aspects, with Notes on Davos Platz, Wiesen, St. Moritz, and The Maloja. By A. Tucker Wise, M.D., L.R.C.P., M.R.C.S. Second edition. London: J. & A. Churchill. 1885.

The attention that has been given of late to high altitudes in the treatment of disease makes the work of Dr. Wise a timely one, though more especially so for European physicians. The book contains a few chapters on the physiological effects of high altitudes, cold, ozone, etc. The rest is devoted to descriptions of the Alpine resorts, and to plain, practical directions as to how to dress and live in these places. An excellent map prefaces the book

Reports of Societies.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 5, 1886.

BEVERLEY ROBINSON, M.D., PRESIDENT, IN THE CHAIR.

NERVOUS DEAFNESS.

DR. SAMUEL SEXTON presented a case of nervous deafness, occurring in a case of supposed poliomyelitis. The patient was a Swedish sailor, who, after a difficult cruise around Cape Horn, was exposed to the heat of a tropical sun. This occurred five years ago. Immediately afterward he became "blind" while in the harbor of Rio Janeiro. Four months later on, while on board ship, the lower limbs became paralyzed, then the upper extremities and face. Five months later *he became suddenly very deaf.* He now states that for the past three years he has been drifting about in foreign hospitals, with, possibly, some improvement in the hearing. His appearance is peculiar, especially the facial expression, there being paresis of the region below the eyebrows. He gives no history of syphilis or accident, and there appears to be no anæsthesia or paralysis of the bladder or rectum. He has had no pains in the head or marked vertiginous symptoms.

Present condition of the hearing organs.—The drum-heads do not indicate any serious departure from health, but he is very deaf to ordinary conversation, in fact hears loud voice only. He takes cognizance of what is said to him hesitatingly, and is, therefore, "slow of hearing," so to speak.

Dr. Sexton drew attention to the method of employing the tuning-fork as a means of differential diagnosis, as between affections of the transmitting apparatus of the middle ear and those of the perceptive tract of the inner ear; thus, he showed that in applying the vibrating fork to the vertex, the result was negative; to the globella, a sensation was imparted which the patient said was rather felt than heard; while vibrations propagated from contact with the teeth are, though best conducted of any, heard but faintly. Granting that the middle ears are fairly normal in this case, we should, of course, have defective perception from bone conduction, as well as from aërial; but since the defect in this case lies almost exclusively in the perceptive tract of the ear, the sounds are better heard aërially when the vibrating fork is held close to the ear. Were the transmitting apparatus of the middle ears only affected, the patient would hear the vibrations of the fork through the tissues loudly.

The patient was brought before the Society on account of the extreme rarity of "nervous" deafness, and to obtain from the members suggestions as to the diagnosis of the brain trouble and the treatment of the case.

DR. WILLIAM T. BULL read a paper (see p. 265) entitled,

SOME SURGICAL POINTS IN THE TREATMENT OF PERITYPHLITIS.

DR. GEORGE F. SHRADY said he agreed in the main with what Dr. Bull had said. There was no argument against the evacuation of pus as soon as it could be discovered, and the needle gave us the surest indication. The presence of pus indicated the walling-in process by adhesive inflammation; and while it was well to operate early, it was well, also, to be sure that the time for operation had come. He had been led to believe that, occasionally, some of the early symptoms were masked. In fact, the first case reported by Dr. Bull seemed to be one of that kind, as it was not a case in which pus had formed within forty-eight hours. The rule given by the late Dr. Parker as to the time when the incision should be made was between the fifth and the twelfth day. He also advised the early use of the needle. In one case in which an incision was made on the sixth day a burrowing abscess formed, and a second operation was performed five or six days afterward.

With regard to perforation of the intestine, he had had one well-marked case, occurring on the tenth day in a farmer who had the characteristic symptoms, as pain, vomiting, localized swelling, dulness on percussion over the right iliac fossa, and œdema of the integument—which he had noticed in four or five cases, and had come to regard as rather pathognomonic of deep-seated inflammation. On the seventh day he prepared to operate, but the patient had a movement from the bowels, and there was pus found in the stool, which indicated that the abscess had ruptured, and recovery took place without operation.

Dr. Shrady thought it important, in cases of typhlitis or perityphlitis, to keep the patient perfectly quiet, and give nature an opportunity to wall in the abscess. He knew of two cases in which death took place, where due regard to these points had not been observed. In one, rupture of the abscess occurred while attempting to get out of bed, and in another, vomiting broke up recent adhesions. He believed in an early operation when a positive diagnosis could be made and the presence of pus could be ascertained, and the needle was the only sure guide.

DR. GIBNEY thought the argument given by Dr. Bull for early operation was very convincing. If he understood correctly, Dr. Shrady thought it advisable to wait for the walling-in of the abscess to take place.

DR. SHRADY thought the abscess was, as a rule, already walled in before we got a chance to attack it. In fact, plastic lymph was almost invariably thrown out before the pus was formed. It was wiser to wait a reasonable time for these adhesions to become firm than to run the risk of breaking them up by operating too early.

DR. GIBNEY said the cases reported by Dr. Bull were extremely interesting; but especially the one in which he made an incision after finding pus with the needle, and without finding any more pus, and the boy recovered. The query arose, Where did the pus drawn by the needle come from?

DR. BULL said he did not know. No pus could be discovered after the incision was made.

DR. GIBNEY said he asked the question for the purpose of leading up to another; that is, whether an abscess might not exist, and even the patient walk about, and yet make a recovery with apparent resolution. He had seen a number of cases in which there was apparently idiopathic perityphlitis; that is, simply a cellulitis about the vermiform appendix not depending upon any foreign body in the appendix. He had seen quite a number of children, varying in age from eight to ten years, who presented the characteristic deformity of hip-disease, yet who exhibited but little constitutional disturbance except a localized cellulitis. There was, however, no spinal disease, and these children made a good recovery with resolution taking place, and at the same time he had thought he was able to detect fluctuation. He was not allowed to go further in the way of diagnosis, because it was against the rules of the institution with which, at that time, he was connected; and he had wondered what became of these patients. He would ask Dr. Bull whether they could not have been ambulant and stil have perityphlitis, or whether there was such a thing as primary idiopathic perityphlitis recognizable.

DR. G. L. PEABODY had had a somewhat melancholy experience, and the result had led him to be more radical than even Dr. Bull had expressed in his paper. He had made a large number of autopsies in such cases, and had made five within the last four months. He was convinced that many lives could be saved by early and radical interference, even where pus could not be detected by the needle. He recollected distinctly the case of a child who presented all the usual symptoms of this disease, and where the needle did not detect pus, although freely and skilfully used; but the autopsy revealed a small abscess behind the cæcum, which perhaps might have been relieved by more extensive operative procedure. Such

an operation was as likely to do well as any other incised wound, provided vital structures were not injured. He had seen quite a number of deaths from general peritonitis in which he believed life could have been saved if the operation had been resorted to early.

In the five cases in which he had made autopsies within the last four months, one had several accumulations of pus, such as could not be reached by a surgical procedure. He thought that the physical signs of dulness and sensation of resistance were rarely directly proportionate to the amount of pus which the tissues contained. In such a case as Dr. Bull had reported there were dulness and a sense of resistance in the region of the cæcum, and, although the needle detected pus, it detected only a few drops; but an operation, quite radically performed, did not reveal any considerable amount of pus, yet there was a necrotic condition of connective tissue around the cæcum all the way from the rim of the true pelvis to the diaphragm, without forming much of a collection of pus. If that patient had been operated upon early perhaps the inflammation could have been cut short.

He thought we were a little apt to be led astray by finding acute general peritonitis at the autopsy, which might lead to the supposition that the pus was not sacculated; whereas such an inference could not be properly drawn, because the general spread of inflammation may have been a secondary affair, and in consequence of the operation having been delayed too long or the patient moving about too much.

He made an autopsy several years ago in which there was no collection of pus near the cæcum, but there was pus about the peritoneal cavity, and the deduction was that the operation would not have done any good. But Dr. Peabody's inference was that if the operation had been performed early very much good would have been done.

In only one of the five cases was there any considerable quantity of pus in the peritoneal cavity, but in two there was acute general peritonitis, with pus sacculated about the vermiform appendix and behind the cæcum.

It seemed to him that in the hands of skilful surgeons, as Drs. Bull and Shrady, the operation was quite devoid of danger, and he would not turn aside from it because pus was not reached by the needle; for small collections of pus might be missed by the puncture, whereas a more extensive operation would evacuate an abscess.

Dr. A. B. Ball remarked that the symptoms of general fatal peritonitis as the result of perforation might run their course in from eighteen to thirty-six hours, and develop in the midst of perfect health.

Dr. Peabody said that even in such cases surgical interference should not be precluded.

Dr. Sexton asked concerning the difficulties of diagnosis in protracted cases of this kind.

Dr. Ball thought that Dr. Shrady had partly answered the question, because he had called attention to the fact that people do have large collections of pus and yet are actually able to walk about, and present only very trifling symptoms. He did not remember to have seen such a case, except once, a good many years ago, and that was an abscess following a stab-wound in the lumbar region. The man was sent out from Bellevue Hospital, supposed to be perfectly well. He walked as far as the corner of the street, and was thrown off from the street car, and died a few hours afterward, and it was found that there was a large peri-nephritic abscess which had burst into the peritoneal cavity. He did not believe that such occurrences were very common, but he certainly believed that they existed. So far as local signs of abscess were concerned, they could be questioned, because there might be a certain quantity of gas within the cavity which did away with dulness on percussion.

With regard to ambulant cases, he recalled a remarkable one of this kind which occurred several years ago, where a young lady had been ill in the country with what her attending physician said was inflammation of the bowels. She convalesced, and finally came home. She was able to sit up in the cars, and rode from the depôt in a carriage, and passed a very comfortable night after reaching her home. In the morning she came down to breakfast, and after her breakfast played on the piano. About two hours afterward she was suddenly taken with severe coughing, accompanied by a sense of suffocation and profuse expectoration of pus. Dr. Ball saw the patient within fifteen minutes after this occurrence, and found her dying, and she did die within a few minutes. The autopsy showed that the girl had had an immense perityphlitic abscess which had burrowed, formed a large collection of pus between the liver and diaphragm, and had burst into the right lung. At the time of the autopsy more than one pint of pus was found between the diaphragm and the liver.

Dr. Gibney said that he would not oppose early operations or exploration, but he simply spoke of the cases which he had mentioned, because patients do sometimes go about and resolution occur. He would not wish, however, to go so far as Dr. Peabody recommended, nor so far as Dr. Bull had advised.

Dr. Kinnicutt said that according to his experience, and he thought it was also that of all the gentlemen present, attacks of inflammation in the region of the head of the colon were very common, and yet he thought it was often quite impossible to determine what was the source of irritation or inflammation. He was taught that in a certain number of cases distention of the cæcum from accumulation of fæces was one of the causes, but he had not been able to convince himself that such was the case. One reason why it had been so taught, probably, was because the evidence of tumor had been obtained, and it had been regarded as a tumor formed by fecal accumulation; but he believed that it was simply a tumor produced by inflammatory exudation, which in many cases undergoes spontaneous resolution. He was firmly convinced, however, that if, after a period of a week, at most ten days, some elevation of temperature was maintained, with constipation and evidence of tumor in the right iliac fossa, an exploration should be made. He had not seen a case go beyond ten days without suppurative process existing, and if it does exist the sooner an exploratory incision is made the better it is for the patient. He would ask if the experience of the other members coincided with his own, in that after a period of ten days, with evidence of distinct tumor in the right iliac fossa and elevation of temperature, suppuration did not exist.

Dr. Peabody said he had seen one case in which all these symptoms were present, and where repeated puncture failed to detect pus, but fever continued; yet the result showed that conservatism was wise, because the boy got well. It was a case, however, in which the symptoms were not very well marked, yet they were so distinct that three competent men who saw the patient agreed that they were present.

Dr. Kinnicutt said that perhaps he should have been more definite, by including only cases in which evidences of tumor were perfectly distinct. There was another point to which he had not heard reference made, and that was the tendency to recurrence of this trouble in patients who had had it once. He had seen a patient with three recurrences, and in each instance resolution took place.

Dr. A. A. Smith asked if any of the members present had noticed any relation between this disease and mental depression. He had seen three cases following very great mental depression, one occurring in a gentleman who met with great reverses in business; one in a lady who suffered from mental depression; and another in a gentleman who was afflicted with loss of both family and fortune.

Dr. Ball said that he had seen about fifteen cases, and he had not observed this element.

Dr. Gibney suggested that mental depression might

interfere with digestion, and that indigestion might be a predisposing cause to such intestinal trouble.

Dr. Smith regarded the two conditions as merely coincident in his cases.

Dr. Ball referred to a point of some importance, namely, that perityphlitis sometimes runs its entire course without elevation of temperature; that suppuration may occur within the first few days of the disease, after which the fever subsides, while the suppurative process goes on. He saw a case three years ago, occurring in a little boy, where, after three or four days, the fever subsided entirely, tenderness disappeared, and there was such a marked amelioration of symptoms that both he and Dr. Sands, with whom he saw the patient in consultation, regarded it as a case in which there was no suppuration. The boy, however, was very suddenly seized with abdominal pain, fell into collapse, and died within ten hours, and on examination it was found that the abscess had ruptured into the peritoneal cavity and excited a fatal peritonitis. There were in this case the usual symptoms of perityphlitis, with the existence of tumor and distinct resistance on palpation. The needle had not been introduced.

Dr. Shrady referred to a case in which resolution took place and in which there was tumor, fever, and limited dulness on percussion. The symptoms continued seven days. The patient was a lad twelve years of age. The mother objected to the use of the exploring needle. The patient was kept quiet, and is alive to-day. He could also refer to the case of a medical gentleman, who had had two attacks from which he recovered without an operation. He believed that in both these cases perfect rest gave nature an opportunity to cure the disease by resolution.

Dr. Peabody thought that one such case as that related by Dr. Ball, where the boy died of rupture of the abscess, was sufficient to counteract the force of a hundred such cases as had been brought forward by Dr. Shrady.

Dr. Shrady merely referred to these cases as exceptional ones. There was, however, never any argument against the evacuation of pus, wherever it might be. He believed that the introduction of the aspirating needle could always settle the existence of an abscess of any size.

Dr. Ball said the question arose whether or not it was proper, in cases of perityphlitis, to thrust in a needle within forty-eight or seventy-two hours.

Dr. Peabody thought it was not, and yet he thought it would not do any harm.

Dr. Bull said that if the disease was ushered in with acute symptoms, and the patient was evidently going to the bad, it would be undesirable to delay the insertion of the needle. He thought it was not desirable to insert the needle if there were no local symptoms whatever. The operation itself was harmless, and with the application of cocaine was not painful.

The point which he wished to make was, that the general symptoms were not to be looked upon, and that the allowance of time, either of ten days or forty-eight hours, should be left entirely out of the question. Given a person with sufficient fever, with local signs which point to the existence of an exudation into the iliac fossa, the rule should be to explore with the needle at once, and he thought he should agree with Dr. Peabody, that in a case in which the pain was severe, accompanied with fever, and the attack a sharp one, make an incision, even if the needle found no pus whatever. He believed that by this somewhat aggressive kind of surgery more recoveries would be secured than by avoiding the operation.

Dr. Kinnicutt said that he only meant to be understood as saying that he thought the operation should not be delayed beyond ten days. He thought it frequently was indicated, and he certainly would not object to its being performed much earlier. He believed that frequently suppuration occurred very early.

Dr. G. L. Peabody presented a

GALL-STONE

passed per anum by a woman thirty-two years of age. It measured a little more than two by one inches. She had a good deal of pain in the region of the liver, and it was thought that she had colic; but she was not relieved by the medicines usually administered in such cases. She insisted that there was a stone inside of her, as she could feel it move about. The specimen was presented to him by the eminent dermatologist, Dr. George T. Jackson.

Dr. Ball referred to a case in which a gall-stone as large as an average sized potato produced fatal intestinal obstruction.

Dr. W. T. Bull presented photographs which illustrated a plastic operation for the relief of

DEFORMITY OF THE NOSE.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, January 28, 1886.

ALEXANDER S. HUNTER, M.D., CHAIRMAN.

Dr. Malcolm McLean presented the sloughed portion of intestine in a case of

INTUSSUSCEPTION,

which occurred in a boy five years of age, who, when he first saw him, was suffering from all the ordinary symptoms of acute dysentery. After a few hours, on account of extreme tenesmus and some evidence of shock, he concluded that it was a case of intussusception. Began treatment, but did not succeed in reducing it. Dr. Rudisch was called in consultation, who agreed with regard to the diagnosis and treatment, but recommended that the abdomen be opened, to which Dr. McLean objected, on account of the general condition of the patient, and excessive tympanites, etc. The case went on for ten days with complete obstruction, and with continuation of bloody discharges from the anus, and on the eleventh day a small fecal movement occurred, containing a large piece of intestine. The patient since that time has been doing well, although he had had what appeared to be an attack of peritonitis. The interesting clinical features of the case were—complete obstruction for this period of time, with no vomiting whatever. The treatment adopted was the use of large injections of flaxseed tea, the child being inverted and the abdomen kneaded, and afterward inflation. He was able to inject twenty-one ounces of the tea, which was evidence that the obstruction was high up.

In answer to questions Dr. McLean said that he did not use carbonic acid gas, as recommended by Dr. Forest, because he did not think it had any special preference over common air; also, that there was a marked tumor on the left side; and that he did not anæsthetize the child preparatory to injecting the warm flaxseed tea.

Dr. J. H. Ripley thought simple water was as likely to succeed in reducing an intussusception as any effervescing fluid, although a number of cases had been reported of success in the use of the latter. He thought that the administration of an anæsthetic aided wonderfully the use of water.

With regard to abdominal section, he thought that the operation, in most cases, had been performed on the adult.

Dr. H. Griswold said that Dr. Sands operated in one case for him, and the child died of shock at the end of about two hours.

Dr. A. Jacobi said there were two or three cases on record in which laparotomy had proved successful; the number, however, was very small. The only baby on whom he had operated was a child eight weeks old, an unusually young subject. The operation could be completed, but the baby died a few hours afterward.

Dr. J. Lewis Smith then read a paper on

THE TREATMENT OF ACUTE INFANTILE BRONCHITIS.

The subject was considered under two heads: (1) mild, and (2) severe bronchitis. He believed that simple bronchitis could be aborted, or rendered milder, by an emetic employed when the first symptoms appeared. For this purpose ipecac was probably the best. Measures designed to abort the disease, however, were not usually indicated when the patients were first seen; to be employed with success they must be adopted very early.

The treatment for mild, uncomplicated, primary bronchitis was very simple. A favorite mixture of the late Dr. Jackson, of Boston, consisted of equal parts of almond oil, syrup of squills, simple syrup, and mucilage of gum arabic. Of the mixtures in the dispensatory the mistura glycyrrhizæ composita was the best. The compound syrup of ipecac of the French Pharmacopœia was a most elegant mixture.

When the temperature was 102° F., and above, and the respiration correspondingly accelerated, he had been accustomed to use a mixture consisting of sweet spirits of nitre, syrup of ipecac, and syrup of balsam of tolu.

Severe bronchitis.—When the inflammation involved the smaller bronchial tubes localized atelectasis was liable to occur, and also catarrhal pneumonia, which was one of the most dangerous diseases of infancy.

The indications for treatment in a severe case of bronchitis were to promote expectoration, to diminish inflammation, to strengthen the action of the heart, and prevent exhaustion.

In reference to cough there was safety in it, and he seldom added opium to any of his prescriptions which were designed to relieve cough. Although children did not expectorate, the bronchial tubes were as effectually emptied when the sputum was swallowed. To facilitate expectoration two remedies had been used largely, namely, carbonate and muriate of ammonia; the latter was preferred in most cases, except in the advanced stages, when the former might be advantageous as a stimulant.

A favorite formula for the use of muriate of ammonia with him had been muriate of ammonia, one drachm; balsam of tolu, two ounces. When there was great dyspnœa and indications for clearing the bronchial tubes of mucus, this remedy should be administered every half hour. Dr. Smith had not witnessed any marked benefit from the use of senega or squill. To get rid of large quantities of mucus an emetic was sometimes proper.

To sustain the patient and reduce the fever.—He had not noticed any marked reduction of the temperature by the use of quinine, but it seemed to him that it had been useful as a heart tonic administered in small doses. For a child one year of age, half a grain to one grain. Antipyrine might be of service, but care should be exercised in its use. In a vigorous infant, suffering from bronchitis without or with only a very slight amount of pneumonia, it might be used. Digitalis as a heart tonic was one of the best which could be employed. Alcoholic stimulation was necessary in severe cases; two or three drops of whiskey in water, for each year of age after three months, given hourly or every second hour.

External treatment.—Leeching and vesication have been abandoned. Slight irritation of the surface affords relief, and for this purpose he had been accustomed to use a flaxseed poultice, first rubbing the chest with camphorated oil in young children, and using a mixture of mustard and flaxseed, one to sixteen, in older children, enveloping the chest with the poultice and covering it with oil-silk. In those cases in which there was hurried respiration, accompanied by continued moaning, to cover the chest posteriorly and anteriorly with a poultice, and over the whole place an oil-silk jacket would afford marked relief.

In robust children the application of cold to the chest during the acute stage, as recommended by Henoch, of Berlin, might be of more service than poultices. For all infants under six months of age, however, poultices were preferable.

Change in position of the child he regarded as a most important element in the treatment—laying the child first upon one side and then upon the other, and upon the back.

The Chairman invited Dr. A. Jacobi, to open the discussion, who said that whenever Dr. Smith read a paper very little, if anything, remained to be said. There were some points which he would like to impress upon those present who had not seen a great amount of practice, and who would doubtless see more of these cases hereafter. One of the principal points to which allusion had been made, and of which he wished to speak, was the use of *opium* in these cases. We could not do well without opium in many of them, because there was so much irritation; but he would emphasize the necessity of giving as little as possible. If it was to be given at all, give a good-sized dose at night, for the purpose of securing a number of hours of sleep. He would express his conviction that in no small number of cases of capillary bronchitis and acute pneumonia in adults, the patients died in part of their disease, in part of the influence of opium. Certainly opium would suppress expectoration, and without expectoration bronchitis and pneumonia were almost invariably fatal.

There was one great expectorant which Dr. Smith had not mentioned, and that was *water*. Where was the expectoration to come from unless there was fluid in the body? It was all well enough to give muriate of ammonia and expect it to liquefy the expectoration; but the liquefaction could not take place without plenty of water, and the chief danger was that water was not supplied in sufficient quantities to young infants, older children being able to ask for it.

Another important point was the regulation of the temperature and moisture of the atmosphere in the room; this is especially important in all cases of so-called dry bronchitis.

With reference to the use of *digitalis*, he believed that two or three large doses in twenty-four hours were preferable to small doses frequently repeated. A child one year of age would take one grain of digitalis, three times a day, for as many days as would be required, and the effect would be much better than if the remedy was used as it was usually employed.

Another exceedingly valuable expectorant was *camphor*, the effect of which was permanent, and it was more easily taken than carbonate of ammonia. A child one year of age might take one-quarter, one-half, or even one grain of camphor, rubbed up with glycerine as often as every hour or every two hours, and in bad cases of bronchitis or pneumonia where expectoration was wanted he had not seen any expectorant which had served him a better purpose.

Turpentine, also, by inhalation, was an excellent expectorant. Put a tablespoonful or two tablespoonfuls of spirits of turpentine into the kettle of water which is kept in the room to moisten the atmosphere, and the air will be impregnated with the vapor of turpentine, which will greatly benefit the patient.

The Chairman invited Dr. John H. Ripley to continue the discussion, who said that he should take issue with Dr. Smith with regard to aborting bronchitis by the administration of an emetic. The inflammation might be shortened, but he did not think it possible to abort it. That, however, was a matter of experience.

With regard to the temperature, it seemed to him in cases of bronchitis limited to the large air-passages, or

involving only the smaller tubes, that a temperature never occurred sufficient to demand antipyretics. If there was a temperature of 102° F. plus, he should search for some other cause for its explanation than the bronchitis. His experience had been that bronchitis rarely afforded a temperature of 102° F., except during its onset.

As to opiates, Dr. Smith and Dr. Jacobi had condemned their use, and he also wished to condemn their use to any very great extent; but, at the same time, he should always think of giving opium to some extent if the cough was frequent and harassing. He did not think it was necessary for a child to keep coughing to prevent collapse of the lung. It was necessary that the child should take deep inspirations, to be sure, which generally would be sufficient, with the use of a small quantity of opium, and the cough, when modified by opium, was sufficient to keep the bronchial tubes open.

Many years ago he learned a lesson from Dr. Jacobi—not the only one by any means. Jacobi said:

Spasm the baby,
Make it cry,
Loud as you can,
The baby will die.

With regard to expectorants, he did not agree with Dr. Smith in beginning their use at the outset of the disease. We should wait until the bronchial tubes began to secrete before administering them.

He thought the best prescription at the beginning of an attack of bronchitis was a combination of veratrum viride and the spiritus mindereri. When the case reached the stage of expectoration he agreed with Dr. Smith that one of the best expectorants which could be employed was the muriate of ammonia; and another good mixture to be used with it was the mistura glycyrrhizæ composita of the dispensatory. Also, he did not know of an expectorant of more value than turpentine, particularly if the larynx was involved.

With regard to quinine, he did not use it at all in the treatment of bronchitis. Dr. Ripley then spoke of bronchitis occurring with rachitis, in which cod-liver oil, but better, linseed oil, was of special service. He also spoke of a form of circumscribed capillary bronchitis, and what might be denominated a malarial bronchitis, in which quinine was the remedy *par excellence;* but to be used effectually it must be given in large doses; for a child one year of age, fifteen grains daily.

Dr. Ripley advocated the use of poultices, and employs thick poultices. The object of the poultice was to afford protection from the air and to give moisture and heat, and he therefore used at least a pound of flaxseed meal, which made a thick poultice that would envelop the chest of a child, and would not need changing oftener than every five or six hours.

Dr. John C. Peters was asked to continue the discussion, and said that one remedy, which was the best of all expectorants, and which allayed the cough, had not been mentioned, and that was potash. The form in which he usually prescribed it was the liquor potassæ, one drachm to four ounces of water, and he very frequently used anise-seed water, which of itself was somewhat soothing. All of the alkalies, but more particularly potash, increased the ciliary movement of the bronchial epithelia, the only way in which expectoration was brought forward where it could be reached by cough. Besides, a solution of potash would dissolve mucin, while simple water would not. He had almost abandoned the use of ipecac, except perhaps in small tonic doses. When there was great congestion and dyspnœa the administration of small doses of calomel, sufficiently large, however, to move the bowels, would relieve the heart and lungs, and render *digitalis* more active than it otherwise would be.

With reference to external treatment, he had used flannel chiefly, perhaps covering the chest with cotton. He thought that the frequent changing of poultices exposed the infant too much.

With reference to change of position, he had been in the habit of placing the child on the face, and had found it very beneficial.

He never used quinine as an antipyretic, but thought it beneficial in preventing the migration of leucocytes.

Dr. Joseph E. Winters said that while, perhaps, acute bronchitis could not be aborted, the inflammation certainly could be minimized. During the time when the congestion was limited to the bronchial artery, remedies which reduced the force and frequency of the heart's action would reduce the inflammation, and for this purpose he employed veratrum viride, already mentioned by Dr. Ripley, or aconite; as a reliable article of veratrum viride was somewhat difficult to obtain, he frequently used the latter agent. This expectation, however, was realized only in cases of acute primary bronchitis.

After this his method of treatment was to use derivatives, and then mild cathartics, consisting chiefly of alkaline mixtures.

The second indication was to prevent accumulation of catarrhal secretion, as here occurred all the deaths. For the prevention of the accumulation of this secretion he used stimulating expectorants, and they varied according as to whether the expectoration was thin or viscid. In this condition cough also became remedial. During the catarrhal stage he combined camphor with other agents in a sufficiently concentrated form to excite a cough, which would, in part, be voluntary. Besides, he applied stimulating liniments to the surface of the chest, which would provoke deep inspiration. For this reason he thought that large poultices were dangerous, and that putting a pound of flaxseed, mixed with water, upon the chest of a child one year of age, would materially interfere with respiration. He preferred the oil-silk jacket, or, perhaps, spongiopylin, with cotton batting and oil-silk. The oil-silk was generally sufficient, with the use of a stimulating liniment, applied by putting the hand under the jacket, without exposing the chest of the child at all. He always insisted upon the following order in most of these cases: First, make the external application, then administer the expectorant, which would excite a cough, and then administer an emetic, and do all this at bedtime.

Opium became a dangerous remedy in young children, and he thought chloral did equally as well. When the secretion was watery and excessive, camphorated tincture of opium might diminish cough and secure rest, but it was not often indicated.

As to whether capillary bronchitis existed independently of broncho-pneumonia, he had his doubts, because when capillary bronchitis was found at autopsy it was associated with more or less of broncho-pneumonia.

Dr. H. D. Chapin made special reference to the use of bromide of sodium, which he had used with good results. The use of opium had been pretty well condemned by the speakers by whom he had been preceded; and even in the doses recommended he had seen, it seemed to him, unfortunate results due to its use. In rachitic children he had noticed a more rapid and a more marked narcotic action produced by opium than in otherwise healthy children. In one case he felt quite certain that the brown mixture, regarded as perfectly safe in ordinary cases, nearly caused the death of his patient. For some time, therefore, he had used the bromide of sodium, and although it did not act rapidly, yet by giving it continuously it produced a sedative effect which had seemed to him to be safe and beneficial. He would be more afraid to use chloral than opium.

With reference to cases of mild bronchitis, he thought one of the best remedies was to put the child to bed at the outset, and when this was done the large majority of children would get well without special treatment.

Dr. J. H. Fruitnight spoke of the use of iodide of potassium in the second stage of the disease, especially when the secretion was viscid, administered in doses of one-fourth to two grains, according to the age of the child. He favored the use of oil of turpentine combined

with balsam of fir, and the use of small poultices, containing mustard in the proportion recommended by Dr. Smith.

Dr. Goelet spoke of the administration of medicines to children by means of a medicine-dropping tube, by which one or two drops could be given at a time, and in this manner the entire dose could be administered, thus securing a more uniform effect of the remedy.

Dr. L. Emmet Holt spoke of bronchitis occurring in children suffering from malaria, in which the bronchial affection yielded only to full doses of quinine. He was indebted to Dr. Ripley for first calling attention to these cases.

The amount of spasm of the bronchi which occurs in some of these cases he had looked upon as one of the signs of rachitis, and in the cases in which he had had opportunity to make an autopsy he had rarely failed to find evidences of rachitis. In these cases the amount of the catarrh is very small, and the amount of spasm is very large, and they are rarely benefited very much except by cod-liver oil and general tonic treatment.

At one time he was averse to the use of ipecac in the treatment of bronchitis in children, but a further trial of the remedy had given, in some cases, very much benefit. A very useful agent, according to his experience, was a hot mustard foot-bath. He had used camphorated tincture of opium, but not in large doses. Chloral, administered in small doses, had been beneficial in nearly all cases.

Dr. Winters wished to emphasize the matter of change of position, of which he had omitted to speak previously. It had been his custom to place the child prone, and he regarded change of position as one of the most important measures in the management of infantile bronchitis.

Dr. Jacobi made additional remarks with reference to those cases in which there was more spasm than bronchitis, referred to by Dr. Holt, and in which the ordinary treatment was of but little avail. There were a number of cases in which a diagnosis was very difficult indeed. When either a child or an adult was seen with all the symptoms of bronchitis, when nothing is known of the beginning of such an attack, and the question arose whether the case was one of bronchitis or simple asthma, it turned out in many instances to be asthma, such as was seen in adults. The fact was that asthma occurred very much more frequently in infancy and in children than we had been aware of. Such attacks would come on very suddenly, and were relieved by the administration of a narcotic, just as it was when it occurred in an adult. Thus a good dose of chloral or opium would do all that was temporarily necessary; afterward the treatment began, and it consisted of measures intended to remove the peri-bronchitis, which was almost always present in these cases. Here the iodide of potassium deserved all the credit which it had ever had in the cure of asthma. In such cases it was also well to study the condition of the nose, especially where there was not much known of the history of bronchitis and peri-bronchitis.

With reference to the association of constitutional diseases with bronchitis, syphilis gave rise less to bronchitis than to interstitial pneumonia. Rachitis might enumerate among its first symptoms hypertrophy of the bronchial and tracheal glands. It was not necessary that the cervical glands be enlarged, but those behind the clavicle were swollen. Again, the thymus gland, which normally had disappeared when the child had reached the fifth or sixth year of age, remained large in rachitic children, and in the majority of cases in which chronic bronchial catarrh existed in children under six or eight months of age, and which did not get well under normal treatment, it was probable that in nineteen out of twenty cases dulness on percussion could be elicited behind the manubrium, due to the large thymus and swollen tracheal, bronchial, and mediastinal glands.

Dr. Smith, in closing the discussion, said that it was difficult, of course, to determine positively whether or not bronchitis could be aborted; but he had seen some cases in which he felt quite certain that the disease had been aborted.

With reference to the use of expectorants from the beginning, he had stated in his paper that only in some cases he believed it to be advantageous to begin their use at the outset. As to the use of opium, he recommended that it should not be used in combination with the expectorant, but that occasionally it might be necessary, and when used he had combined it with the bromide of potassium, as he saw no special advantage in the use of bromide of sodium. He had hoped that the use of cold applications to the chest would have been touched upon by some of the speakers.

Dr. Ripley then referred to the use of cold water in the treatment of pulmonary affections in Bellevue Hospital, many years ago, under the direction of Dr. Alonzo Clark, and also Dr. Thomson, but the results were such as made them abandon its use. This referred to the use of cold water in adults.

The Section then went into executive session.

Stated Meeting, February 25, 1886.

Alexander S. Hunter, M.D., Chairman.

Dr. Robert A. Murray read a paper (see p. 267)

ON THE MANAGEMENT OF BREECH PRESENTATIONS.

The discussion was opened by Dr. H. J. Garrigues, who said that the general management of breech presentations was so well understood that he would direct attention to only a few points on which there was still difference of opinion, and on which the experience of the members would be interesting.

It was a mooted point whether or not the forceps should be used in delivering the head. Most authorities reject the forceps under these circumstances. Where the child was dead he had found the use of the forceps advantageous.

The temptation, in a case of breech presentation was, almost always, to do too much. If there was no disproportion between the child and the pelvis the delivery was very easy, and the best thing to do was to let the case take its natural course. But if there is even a slight disproportion between the child and the pelvis, the proper thing to do was to pull down a foot, which placed the case within the control of the accoucheur, who could thereby deliver the child at once and at any desired time.

When the breech has entered the cavity of the pelvis, a fillet should be passed across the groin, and thus the operator was given control of the child. The blunt-hook was altogether too severe an instrument to be used here. Some had advocated the use of the forceps under these circumstances. That was largely a matter of experience, and it would be interesting to hear the experience of the members on this point.

Dr. Charles Jewett, of Brooklyn, thought that the profession at large was not sufficiently familiar with the technical methods of the management of breech presentations, and were practitioners more familiar with the management of breech presentations version might be resorted to more frequently than it was, and with much better results than the use of the forceps.

The method of managing the head, which he practised most, was the Smellie-Beak, forking two fingers over the neck, and placing two fingers of the other hand in the canine fossæ. When this fails, he uses the forceps, to the cautious use of which he could see no objection.

With regard to the application of the forceps to the breech, his impression was that it was not in the disrepute which might be inferred from what had been said. On the other hand, he thought that the application of one blade over the sacrum and the ilium, and the other over the posterior surface of the opposite thigh, that which lies anteriorly as the thighs are flexed, had proved a satisfactory method in good hands. He repudiated the application

of the forceps over the trochanters. He had depended mainly on the manual methods of extraction, the most effectual being the fillet, when a foot cannot be brought down. As to the difficulty of passing the fillet, it had occurred to him that the Elliot uterine repositor might be used with advantage for passing the tape with which it was to be drawn into position.

He recommended it as good practice to visit the patients a week or so before expected confinement, make an examination of the abdomen, and, if a breech-presentation was detected, to change it into a cephalic presentation at once. He referred to a recent case in which he changed the presentation three weeks before labor.

Dr. Egbert H. Grandin referred to a paper by Olivier, who recommended application of the forceps in cases of breech presentation in which the legs were completely extended on the ventral surface of the child. He had not seen such a case, but should he encounter one he should be tempted to use the forceps rather than introduce the hand to the fundus in search of a foot.

He also would apply the forceps over the trochanters rather than make traction with either the fillet or the blunt hook.

With regard to examination of patients before labor, he regarded it as something which all should do, and if it was found on abdominal palpation that the breech was presenting, and it was about the end of the eighth month, it would usually be easy to change it to a cephalic presentation.

Dr. Malcolm McLean said that the highest rate of mortality for the child in breech cases he had been able to find reported was *two* per cent. A few years ago he took occasion to obtain the personal experience on this point of a large number of eminent obstetricians in this city, and the result was at variance completely with the statistics given in the text-books. One gentleman told him that there was no necessity of losing any children in cases of breech presentation. The late Dr. Elliot taught that one in five children would die in these cases. So far as his own experience went, he had not lost a child, and he had had twenty cases.

If there was danger to the child, as great as represented by the statistics in Dr. Murray's paper, Dr. McLean thought that the presentation should be regarded as an abnormal one and be dealt with accordingly.

But if the mortality was only almost the same as in cephalic cases, why perform cephalic version before confinement? He held that it was unnecessary. If delivery by the breech can be made almost as safe as with cephalic presentation, he regarded the *meddling* as the cause of the death of the child.

His plan of management had been, in every case in which the measurements of the pelvis were apparently good, but the mother was becoming exhausted, to introduce the whole hand into the vagina, measure the pelvis thoroughly, ascertain the exact position and presentation of the child, and in breech presentation bring down a foot, which could almost always be done without difficulty. Any pelvis which will allow the body of the child to come down into it will permit the passage of the hand alongside the child. He regarded the fillet and the forceps operation as troublesome, if not dangerous. He was opposed to the use of the forceps to the breech of the child. The foot gives something with which to make traction, and with which to make traction at the exact time when traction should be made. When the breech of the child is well through the pelvis, *traction should cease*, and the child should be delivered by pressure from above.

As to the delivery of the head, the moment the body of the child is sufficiently delivered to get hold of it, the temptation to pull is so great that up goes the chin and is locked, and then comes the struggle, and the child dies, not of suffocation, but as the result of traction on the spinal cord. The instant the arms are brought down he depends entirely on external pressure over the uterus. If the head locks in the pelvis, it becomes a question whether or not forceps should be used.

Dr. H. J. Boldt favored bringing down a foot, and had not seen the necessity for using the forceps, and in the only case in which he used the fillet, the child was lost.

Dr. J. H. Fruitnight referred to a case in which he applied the forceps over the trochanters, delivered the child safely and without injury to the mother. He published the case about ten years ago, in the *Virginia Medical Monthly*, and it was the first in this country in which this method had been adopted. At the meeting (Northwestern Medical Society) when he first reported this case, Dr. T. H. Burchard related two cases in which forceps were applied to the breech; in one of them by mistake, as it was supposed to be a case of cephalic presentation.

He has discarded the blunt-hook in these cases. He believed that the chin was frequently locked under the pubis by ill-advised traction. He referred to a case in which he found a combination of spina bifida and breech presentation that had given rise to difference of opinion concerning the presentation.

Dr. Garrigues thought that the use of the fillet and the forceps were to be compared, and not the bringing down of a foot and the use of the forceps. When the child is not far enough down to get hold of it with the fingers, but in the cavity of the pelvis, he prefers the fillet to the forceps; if unable to apply the fillet he uses the forceps.

Dr. Fanning referred to a case in which he completed delivery of the head with the forceps, with safety to the child and the mother. He also referred to recorded statistics of nine hundred cases, in which there were fifty of breech presentation, with one death.

Dr. W. E. Forest saw no reason why the forceps should not be applied every time the head was delayed at all in delivery, and was unable to see why it was not safer and speedier than to rely upon pressure from above. As soon as he discovers that he has to deal with a breech presentation, he sends at once for his forceps, and when the body and arms have been delivered and the head is not delivered immediately, he uses the forceps; the long forceps without handles, devised by the Chairman. He was thoroughly against traction on the body of the child, and equally strongly in favor of the use of the forceps for delivering the delayed head.

Dr. Goelet had seen the fillet produce injury, which, if not dangerous, was exceedingly disagreeable.

Dr. J. H. Emerson asked concerning the time when the change of presentation by external manipulation should be effected.

Dr. Jewett thought that in most instances it should be done near the time of labor, and Dr. Grandin said certainly in the eighth month, and he would prefer to make the change earlier.

Dr. F. A. Burrall suggested that exactness, with regard to the management of breech cases, would be promoted if the main diameters of the child's head and the approximate diameters of the mother's pelvis were given.

Dr. Murray, in closing the discussion, said that if the child was well-shaped, and the pelvis not extraordinarily large, there would be difficulty in delivery in breech cases. At the same time he felt that Dr. McLean had accepted his view that where there is delay at the brim, the proper course to pursue is to bring down a foot, and certainly that would give control over the head, which is larger than the breech. If traction is made, it should be coincident with pains, and with it continuous pressure over the uterus, if the woman is under an anæsthetic. He did not believe that pulsation in the cord could cease for more than five minutes and the child survive, and if the attendant cannot extract the head promptly, the forceps can be applied.

With regard to changing the presentation before labor, he regarded the time as immaterial, if it be done before

the membranes have ruptured, and the method should be the bipolar of Braxton Hicks.

With regard to the application of the forceps to the breech at the brim, he regarded it as not advisable, and the proper operation would be to bring a foot down. When the breech is in the cavity, a fillet may be used, but if the breech is between the superior and inferior straits, and one finger can be got into the groin, the fillet is of no use.

With regard to the method of introducing two fingers into the mouth, he did not believe that they did much in way of flexion, and that the real flexion was obtained by upward pressure made upon the occiput.

The Section then adjourned.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 27, 1886 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
February 27, 1886.....	5	5	45	2	5	73	4	0
Deaths.								
February 27, 1886.....	0	0	7	2	1	34	4	0

POLYMAZIA.—Individuals having one or more supernumerary breasts are not such rare beings as is generally supposed. In France, Puech collected the records of 77 cases, in 46 of which there was one extra mammary gland, in 26, two, and 2, three. When there is one supernumerary breast it is usually situated below one of the others or in the axilla; when there are two they are most commonly found in the axillæ; and if there are three, the other one is in the neighborhood of the umbilicus. In very rare instances the superfluous gland has been seen on the shoulder, thigh, or back. Men, as well as women, have been found the subjects of this anomaly.—*La Riforma Medica.*

DEODORIZED IODOFORM.—We gave recently the formulæ of Herr Oppler, who makes use of roasted coffee in order to disguise the unpleasant odor of iodoform. A still more simple means is that employed by Brunelli. He mixes one part of finely pulverized camphor with three of iodoform, and claims that in this way the characteristic odor of the latter is completely masked.

AN EXHIBITION OF CEREBRAL TUMORS.—Quite a novel exhibition was one of specimens of cerebral tumors held at a recent meeting of the London Pathological Society. There were twenty exhibitors, and more than fifty specimens were shown. The collection illustrated in a remarkable way the fact that cerebral tumors may occur in any region, and the clinical histories given of many taught only too plainly the lesson that in the great majority of cases the symptoms are diffuse and the lesion cannot be localized. Many of the specimens showed very well the tendency of gliomata, when occurring in the cortex, to remain limited to the gray matter, and their infiltrating tendency when occurring in the white substance.

TREATMENT OF HYSTERIA IN CHILDREN.—As to the direct therapeutic treatment of hysteria in children, Dr. Herz agrees with Henoch, the acknowledged highest authority on children's diseases, that there is no specific remedy for it. Henoch prefers the hydrate of chloral to all other medicines, though he regards morphine as almost equally valuable. The former he prescribes in 0.5 to 1.00 doses (7½ to 15 grains); the latter, both internally and hypodermically, in 0.005 to 0.01 doses ($\frac{1}{12}$ to $\frac{1}{6}$ grain). Inhalations of chloroform, though ordinarily exerting only a transient salutary influence, will be found requisite in the occasional paroxysms involving the laryngeal organs. Arsenic and quinine are highly prized by some practitioners, but they possess likewise no constant value. In view of the so frequently underlying anæmic base, small doses of iron and arsenic, continued systematically for a long period, will invariably be found useful. Warm baths, applied frequently, and lasting fifteen to thirty minutes, fresh air, and nourishing food, are always highly commendable in every case.—*Therapeutic Gazette.*

THE MODE OF ACTION OF ANTIPYRETIC DRUGS.—As a general conclusion to Maragliano's valuable researches, we can advance the theory that antipyretic remedies act by being able to eliminate the two most important pathogenetic causes of fever. In other words, they prevent vascular contraction, and the thus resulting storing up of animal heat, and increase the heat-discharge; besides, they combat successfully the increase of heat-formation by reducing the intensity of the oxidizing processes of the economy.—*Therapeutic Gazette.*

COMPARATIVE ADVANTAGE OF DIFFERENT FORCEPS.—Among the changes which have recently taken place with regard to the forceps, there are two, however, which, I venture to think, require further consideration. The first is with regard to the early period of labor at which instrumental assistance is now advocated by some authorities. The second is with regard to the complicated form of forceps introduced by M. Tarnier, and since variously modified and largely employed by modern obstetricians. For my own part, I can see no reason for instrumental assistance before the os uteri is fully dilated, except in certain cases of complex labor, where immediate delivery may be necessary for the safety of mother or child, and in which it must be unhesitatingly resorted to as soon as the os uteri is sufficiently dilatable. But if obstetric practitioners should ever come to regard it as a safe rule of practice to apply the forceps as soon as the os uteri can be sufficiently expanded to admit its introduction—which in some instances may be done before the occurrence of any true labor pains—it is very probable that the ill results of the indiscriminate and injudicious employment of this practice will outweigh all the possible benefits of its right use. The preference generally given to Tarnier's axis-traction forceps by many British as well as by nearly all French obstetricians, over instruments such as Barnes' original double-curved or my own short forceps, appears to me to be a mistaken one. In operative midwifery, as I have before observed, as in any mechanical problem, it is obvious that there should be a due proportion between the power used and the resistance to be overcome, and that the force employed should be the minimum necessary to accomplish the desired effect. This certainly is not the case in Tarnier's forceps, which I cannot but regard as a needlessly complicated, unwieldy, and, for the purpose for which it was designed, an ill-contrived piece of mechanism. Hence, in my opinion, this instrument is by no means equal to Dr. Barnes' forceps for any cases of difficult labor where the head is detained above the pelvic brim; nor, I will venture to add, to my own short forceps in those still more frequent instances in which the head, having entered the pelvic cavity, assisted delivery may be expedient, as I have found in upward of two hundred and fifty cases in which I have now used this instrument.—*Dr. T. M. Madden.*

THE PHYSICIANS OF GERMANY.—Although the number of physicians in Germany averages 1 to 3,025 inhabitants, their distribution is very uneven. The cities and watering places are especially well supplied. In Bonn there is 1 doctor to 440 inhabitants, in Wiesbaden 1 to 558, in Berlin 1 to 1,063.

The Medical Record

A CONTRIBUTION TO THE NATURAL HISTORY OF PULMONARY CONSUMPTION.

EMBRACING THE CAUSATION AND SYMPTOMATIC EVENTS. BASED ON AN ANALYSIS OF FIFTY-NINE CASES OF THE DISEASE.

BY JAMES KING CROOK, M.D.,

ASSISTANT TO DEPARTMENT OF CLINICAL MEDICINE AT NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, IN CHARGE OF THE INTERMEDIATE TERM.

THE clinical observations which form the basis of the following analytical study were made during the past summer at the chest-class of the Out-door Department of Bellevue Hospital, and at the Clinic for Diseases of the Chest at the New York Post-graduate Medical School. They were begun June 11th and terminated September 19th; with few exceptions the cases were presented to the Class in Physical Diagnosis at the Post-graduate School during the summer session of 1885. It was intended, at the beginning of the summer, to note also the results of therapeutic measures, but the extreme irregularity of the patients in attending the clinics interfered to such an extent with my observations that I was forced in a great measure to abandon this line of research; hence, I have preserved records only of facts relating to the causes and symptoms. These, with unimportant modifications, are presented to the readers of THE MEDICAL RECORD in the subjoined table, in about the same shape in which they were obtained from the patients themselves in the clinic rooms. In regard to the table, it may be said that the facts which it contains, though presented in a brief form, will serve to elucidate the points of inquiry about as clearly, and perhaps more satisfactorily, than separately and fully detailed histories of each case. In a few instances, however, the subjects of investigation seemed to warrant rather more space than could be allotted them in the table; they will be given their proper places in the text.

Before proceeding with our analysis it would seem appropriate to call attention to the following facts:

1. The observations made were in a few instances the result of one examination, opportunity not being afforded to make subsequent ones; in most cases, however, the patients repeated their visits at irregular intervals and the examinations were gone over a second, third, or even a fourth time. Almost without exception the original replies which they gave to my questions were steadfastly adhered to, repeated examinations yielding essentially the same results.

2. In order to guard against lapses of memory and to facilitate the taking of the histories, all of the subjects for investigation were written down for reference at the dispensaries and each patient questioned on each subject, with occasional exceptions, *seriatim*.

3. The notes were made with as much care and precision as were possible, each patient being allowed ample time to reply to the interrogations proposed to him. Nothing was jotted down at hap-hazard, and no case about which there was reasonable doubt is included in the list. The diagnosis in each case was based on a good rational history of consumption, confirmed by a careful physical examination.

It should also be stated that in addition to the cases contained in the table, reference is occasionally made to others which have come under my observation, and of which incomplete records have been preserved, also to statistics of phthisis at the Bellevue Dispensary for the past two years which I have compiled.

In our study of these cases the numerical method of analysis inaugurated by Louis,[1] and so ably followed by Professor Austin Flint,[2] will be observed throughout.

FACTS PERTAINING TO CAUSATION.—*Age.*—The first object of investigation will be with reference to the possible influence of age in the development of consumption. Besides the 59 cases in the table I have preserved records of the ages of 82 additional cases which have come under my observation at the clinics of Professor Burt at the Post-Graduate School, and of 776 cases[3] taken from the clinic-book of the chest class of the Out-door Department of Bellevue Hospital for the years 1883–84. The entire number (917 cases) will be considered collectively. The ages by decades were as follows:

From [illegible] year of age	26
" [illegible]	92
" [illegible]	317
" 40 "	157
" [illegible]	42
" [illegible]	18
" 50 [illegible]	9

These figures represent the ages of the patients at the date of application for treatment; the time of the first appearance of the symptoms, if given, would, of course, increase the earlier decades to some extent at the expense of the later. It should also be stated that these cases were treated at clinics to which children are not admitted, those under twelve or fourteen years of age being referred to the children's classes. The foregoing numerical data accord very nearly with those obtained by previous observers (Walshe, Pollock, Flint, Theodore Williams, Reginald Thompson). Leaving out the first decade, they would seem to indicate that the liability to consumption increases from the tenth to about the thirtieth year of life, and progressively diminishes thereafter. Exactly such a conclusion has been arrived at by nearly all writers on the subject. With due deference to the opinions of many eminent authors, I would express the belief that this conclusion is based on erroneous premises. It has been the experience of medical officers of life insurance companies that the *individual* liability to consumption, instead of diminishing, increases after the age of thirty, reaching its maximum at a period beyond the seventieth year of life.[4] The results of an exhaustive investigation into the subject by A. Wuerzberg, Librarian of the Imperial Health-Office at Berlin, amply corroborates this deduction. The methods of study pursued by Wuerzberg are too elaborate to be considered here; but the following extracts from his report will be sufficiently striking: 1. Out of 10,000 persons between the ages of twenty and twenty-five, $30\frac{2,4}{0,0}$ die annually of consumption. 2. Out of 10,000 persons between the ages of twenty-five and thirty, $36\frac{7,3}{0,0}$ die annually of consumption. 3. The proportion continues to increase, until *out of* 10,000 *persons between the ages of sixty and seventy*, $93\frac{1,8}{0,0}$ *die annually of consumption*[5] (the italics are my own).

If further evidence be needed to sustain this view of the subject, we may consider the statistics of the New York City Almshouse, an institution the average age of whose inmates is over sixty years. According to the Warden's report for 1878, there died in the Almshouse during that year 229 persons.[1] Out of this number pulmonary diseases entered into the cause of death in 151, or *more than sixty-five per cent.* of the cases. It has been my personal experience that upward of forty per cent. of the deaths in this institution are induced mainly by phthisis. It need hardly be said that such a proportion of pulmonary diseases will not be found in a general hospital to which persons of all ages are admitted.[2] The number of cases over sixty years of age in the foregoing table will not seem so insignificant when it is remembered that but a small proportion of persons of that age are seen at dispensary clinics. For example, in 450 unselected cases of all diseases at the Post-Graduate School, only 34, or about 7.5 per cent. had attained that age.

The apparently contradictory results which have been obtained by different students of this subject may be reconciled by a moment's reflection. I cannot do better than to quote the words of Dr. Holden[3] in this connection: "A far greater number of persons are living between the ages of thirty and forty (or the earlier decades) than between fifty and sixty (or the later decades), and consequently there is a far greater harvest for this most prevalent of diseases." From this study of the subject the following conclusions would seem to be justified: 1. The greatest *aggregate* number of cases of consumption are developed between the ages of twenty and thirty years. 2. The greatest *relative* frequency of the disease is far later in life, probably between the sixtieth and seventieth year.

Sex.—Of the 59 cases in the table, 40 were males, 19 were females; of 82 additional cases which I have noted, 51 were males, 31 were females; of 411 cases treated at the Bellevue Dispensary in 1883, in which the diagnosis of phthisis is stated in the clinic book, the numbers were, males, 250; females, 161; in 1884, of 365 cases treated at same institution, 207 were males, 158 were females. We thus find the males in excess in every instance. In the total 917 cases, we find 548 males and 369 females, the males being 179, or more than nineteen per cent. in advance of the females.[4] These results agree very closely with the statistics of the Royal Infirmary of Edinburgh,[5] where the males were greatly in excess of the females every year from 1833 to 1865, the date of the latest report of the institution. For example, in the years from 1843 to 1846, inclusive, the males were 356, females, 217; in 1865 the males were 126, females, 64.

From these facts, then, it would seem that phthisis is considerably more prevalent among males than among females.

Social condition.—This point of enquiry will be of interest only as regards the female patients. It will be considered under the head of *pregnancy*, etc.

Occupation.—Investigations with respect to occupation were made in all the tabulated, and in 22 additional cases, making a total of 81. In four instances no occupation was given. In the remaining 77 cases, 41 occupations are represented, being distributed as follows: General laborers, 11; housekeepers, 11; drivers, 5; machinists, 3; coachmen, 2; plumbers, 2; boiler-makers, 2; carpenters, 2; painters, 2; printers, 2; apprentices, 2; factory employees, 2; sewing work, 2; clerks, 2, and one each of the following occupations—blacksmith, compositor, hatter, street-sweep, expressman, dyer, hod-carrier, fishmonger, fisherman, brass-finisher, cigar-maker, profes-

[1] Nineteenth Annual Report of Commissioners of Public Charities and Correction of the City of New York, 1879.

[2] Some of the inmates of the almshouse, no doubt, have phthisis when admitted, but this fact does not militate against the argument: the institution is designed especially for *old people*, whether suffering with consumption or not.

[3] Loc. cit.

[4] I am informed by Mr. McGowan, the assistant apothecary, that sixty-five per cent. of all the patients treated at the Bellevue Dispensary are females.

[5] Reynolds' System of Medicine, vol. ii. Philadelphia, 1880.

sional equestrienne, stand-keeper, store-keeper, weaver, baker, school girl, porter, boatman, tobacconist, sawyer, telegraph operator, stone-cutter, horse-shoer, wheelwright, night watchman, and musician.

The nature of their occupations would indicate that 42 worked in-doors, 27 out-doors, while 8 (as carpenters, painters, etc.) were engaged both in-doors and out-doors. This shows a considerable preponderance of in-door occupations. It must be remembered, however, that among urban populations, especially in cities as large as New York, a considerable majority of the *total number* are engaged at in-door occupations. In verification of this statement I have made an analysis of 78 unselected male patients with various diseases at the Medical Clinic of the Post-graduate School, with reference to this point. The result was as follows: In-door occupations, 43; out-door occupations, 23; both in-door and out-door work, 16. In the phthisical cases it was observed that the patients who were engaged at out-door work were inclined to attach far more causative significance to their occupations than those who worked in-doors. It is questionable whether the machinist at work in his dusty shop is more liable to consumption than the 'longshoreman or the car-driver who must face alike the burning summer suns and the chilling blasts of winter. Out-door exercise under proper counsel is beyond question one of our most valuable adjuncts in the treatment of this disease, but it is equally as certain that undue exposure to the changeable climate of the Atlantic seaboard in this latitude is as cogent a factor directly or indirectly in its production as the confinement of the factory, the machine-shop, or the schoolroom.

Nativity.—Under this head in the table we find the patients distributed as follows: United States, 29; Ireland, 19; Germany, 3; England, 2, and Austria, Wales, Australia, Newfoundland, and New Brunswick each 1. When compared with the total number of patients attending the clinics during the summer, these figures show a slightly greater proportion of Americans suffering with phthisis than of Irish, and a very much smaller proportion of German cases than of either. One of the natives of the United States was a negro, and this I may say is the only case of phthisis in a person of African descent which I have met with among several hundred consumptives.

Heredity, or family history.—Many of our text-books exhibit a proneness to discredit the statements of hospital and dispensary patients with reference to their family histories. It strikes me that an unjust discrimination is made against this class of patients. They are, as a rule, from the lower grades of society, it is true, and perhaps not up to the average of intelligence, but this does not imply a want of filial regard, and I see no reason why their statements with reference to the diseases or causes of death of their parents may not be trusted, especially when they relate to so easily recognized, and usually so prolonged a disease as the one under consideration. Each of the fifty-nine cases in the table was carefully questioned with regard to his father and mother, brothers and sisters, and other near relatives. The following results were obtained, which, I believe, represents the truth as far as the knowledge of the patients enabled them to state it. In 18 cases direct hereditary histories were obtained; either one or both parents had consumption at the time, or had died with it. Several of these also stated that they had lost other relatives with consumption. In 32 cases no direct heredity could be traced, although several of the patients had lost near relatives with the disease. Four of the cases are marked "suspicious," each of them having lost a parent from pulmonary disease (such as "asthma," "pleurisy," etc.). Five others did not know of what disease their parents had died, and were unable to state whether or not there was consumption in the family. Admitting, then, only the cases in which one or both parents were affected with phthisis, we find that 29.91 per cent. gave direct hereditary histories. These results conform quite closely with those of Walshe,[1] who found twenty-six per cent. of hereditary cases. Loomis[2] found eighteen per cent., Reginald Thompson[3] thirty-six per cent., and Theodore Williams[4] forty-eight per cent. of cases in which heredity or family predisposition was traceable. It has been claimed by some authors that in many cases of consumption heredity is merely a coincidence, that its influence is greatly overrated, and that its frequent occurrence among those of the same family is due to the vicious methods of rearing children in certain families.[5] In order to test some of these statements, I interrogated 34 patients with other diseases with reference to their family histories. Of this number 4, or 11.7 per cent., stated that one or the other parent had consumption, or about eighteen per cent. less than patients with a similar history among the consumptive cases. This difference is too great to be resolvable into coincidence or chance—the result strongly corroborates the theory of a congenital predisposition. It is commonly stated that hereditary cases are developed earlier in life, as a rule, than cases without a congenital predisposition. An analysis of the 18 cases with hereditary histories in the table shows the following results by decades: From ten to twenty years of age, 3; from twenty to thirty years of age, 6; from thirty to forty years of age, 5; from forty to fifty years of age, 4.

We find from the table that 9 of the patients were under, and 9 over thirty years of age; the average age of the 18 cases was about 30.60 years. As far as they go, then, these data would not indicate that hereditary cases are developed with greater proportionate frequency in the earlier decades than cases without an inherited tendency.

The results of Dr. Reginald Thompson,[6] who analyzed a large number of cases with reference to this point, are slightly different from these. The appended table will show the result of his analysis:

	Before thirty.	After thirty.
Non-hereditary [illegible]	[illegible]	173
Hereditary [illegible]	[illegible]	123
Hereditary [illegible]	[illegible]	100

Dr. Thompson concludes that the period of greatest vulnerability is about five years earlier in hereditary than in non-hereditary cases. His figures also indicate that phthisis inherited from the mother is developed earlier in life, as a rule, than when the father is at fault. In forming an estimate of these results, however, the fact laid down under the caption *Age* must not be lost sight of, viz., that the total number of persons living under the age of thirty is far greater than the number over this age.

Extending our inquiry into the influence of heredity further, some interesting facts are developed. In the 18 cases with hereditary histories we find that the mother was at fault in 12, the father in 4, and both parents in 2 cases. Ten of these were males (out of a total of 40 males); 8 were females (out of a total of 19 females), or twenty-five per cent. of the former against more than forty-two per cent. of the latter. This would indicate that the mother is much more apt to transmit consumption to her offspring than the father, and that females are more susceptible to hereditary influences than males.

To be continued.

THE SOCIETY OF THE RED CRESCENT is an association in Turkey corresponding to the Red Cross Society of the Christian nations of Europe. The organization, which had become nearly extinct, has recently been revived through the efforts of Dr. Mavrogheni Pasha, physician to the Sultan. It is expected that it will soon be in condition again to send ambulances into the field in case of war in the Grecian Peninsula.

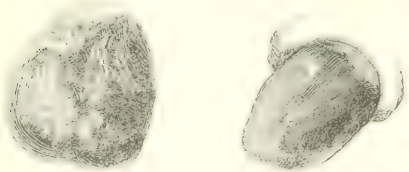
INSTANTANEOUS PHOTOGRAPHS OF THE HEART IN MOTION AND OF PERISTALSIS.

By WILLIAM GILMAN THOMPSON, M.D.,

NEW YORK.

In so far as I am aware, the application of instantaneous photography to the study of the movements of the heart and intestines has not heretofore been undertaken. For some time I have sought a satisfactory method to measure the degree of alteration in size and form of the living heart between systole and diastole, both normally and under the influence of drugs. The methods I have attempted were: 1. To adapt various forms of linear measures, discs, etc., to the contour of the heart. 2. To encase the beating heart in a chamber of some plastic material which soon hardens and is impervious to serum. The chamber communicates with an upright graduated glass tube, and if the portion of the chamber not occupied by the heart be filled with serum, the latter will be driven into the tube at each pulsation with a force proportionate to the strength of the systole. The volume of serum displaced represents the change in size of the heart. The evident difficulty is to make the plastic material fit tightly about the great vessels of the heart without compressing them too much. Moreover, this method only measures changes of the heart in bulk, not in form, and is so difficult as to be wholly unsatisfactory. 3. To throw a magnified image of the pulsating heart upon a screen by a modified magic-lantern ("panopticon"). A scale marked upon the screen serves to measure changes in size, or a ground-glass screen can be used, upon which the heart can be drawn. Any one who has studied the living heart is convinced of the difficulty of making drawings of it while in motion which are at all accurate.



A B

Fig. 1.—Rabbit's Heart in Motion. *A*, full diastole. *B*, full systole.

Cardiographic tracings are useful, but their showing is limited. Hesse has published[1] observations upon the changes in form and size of the pulsating heart. He encased it in a plastic material, which moulded itself about the heart, and hardened so as to give a cast of the greatest expansion. The cast could then be bisected, removed, and used itself as a mould to make solid plaster casts. The heart was afterward artificially hardened by chromic acid, and casts were taken of it in its greatest contraction. Obviously, no intermediate stages between full systole and full diastole could be thus obtained, and, moreover, the systole was not a natural one.

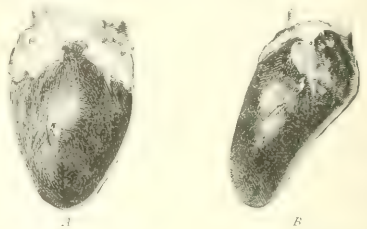
The details of the photographic process with which I have recently experimented cannot be cited here. It is sufficient to say that the photographs were taken indoors in November and December, with direct sunlight illumination, and with an instantaneous drop-shutter giving an exposure of about one-sixtieth of a second. To throw the heart into relief from surrounding tissues which are not distinctly colored, I find it convenient to slip behind it a little piece of celluloid. This affords a good white background, and is easily cleansed of blood, etc., by the common spray of physiological salt solution, which is used to keep the heart moist.

I have taken a large number of instantaneous photographs of the hearts of different etherized animals beating *in situ*, and they demonstrate the following points:

1. For students, and those who have not inclination or facility to study the living heart for themselves, they give a clearer conception of its phenomena than any other method.

2. They are more accurate than drawings or casts.

3. The heart is as nearly in a natural condition, both as to systole and diastole, as is possible with an open chest-wall. Artificial respiration may be easily maintained, and, with assistants, kymographic and other observations may be simultaneously recorded.



A B

Fig. 2.—Pigeon's Heart in Motion. *A*, full diastole: *B*, full systole, produced by application of hot salt and water.

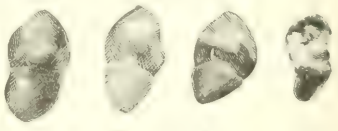
4. A series of photographs may be taken between full systole and full diastole which can be compared and studied at leisure.

5. The photographic method shows more than simple linear measurements, for it gives an accurate periphery as well as diameters, and by perspective gives a fair idea of changes in bulk as well as in form.

6. The movements of the heart as a whole, and the forward and upward movement of the apex, which occurs in many animals, is clearly demonstrable.[2]

7. In addition, the most practical application of the method is the illustration of the changes in the form of the heart produced by drugs. Thus instantaneous photographs of normal systole and diastole are taken, then an injection of digitaline is given and the effect of increased force of the systole is photographed and compared with the normal. The effects of doses of varying strength may be thus compared. The contraction produced by dropping a one per cent. solution of glonoin upon the heart shows exceedingly well in a photograph as contrasted with normal systole. I have also obtained photographs of the transverse section of the ventricles in relaxation, and in the contraction that follows thermic stimuli, even after the heart is cut in two. Any experimental work upon the heart while beating *in situ* may be accurately photographed, and many details become apparent when studying the photographs at leisure, which are otherwise almost impossible to observe, or quite impossible to record at the time of observation.

8. The negatives, placed in a magic-lantern, show admirably upon a very large scale.



A B C D

Fig. 3.—Frog's Heart in Motion. *A*, normal diastole: *B*, normal systole: *C*, increased systole produced by hypodermatic injection of digitaline: *D*, increased systole produced by local application of glonoin, one per cent. (The lower half of [illegible] the background.)

The series of instantaneous photographs which I have taken of peristaltic movement in the intestines show plainly the effects of progressive degrees of contraction of both longitudinal and circular muscular fibres, and the effects of stimuli, chemical, thermic, mechanical, etc.

[1] Fr. Hesse, Beiträge zur Mechanik der Herzbewegung. Archiv f. Anat. u. Physiol., S. 328, 1880.

[2] In the cuts the darker and lighter varying shadows exist by the moving heart which make the [illegible] photographs have been omitted.

Thus in the elaborate researches of Nothnagel, with saline cathartics, he says that certain salts of potassium produce a localized peristaltic wave, while certain salts of sodium produce a wave which travels toward the pylorus. Such facts can be made very real by, for instance, placing a little potassium tartrate upon the surface of a portion of mesentery, and taking a series of photographs of the changes in form and position of the intestine which ensue as soon as the drug is absorbed.

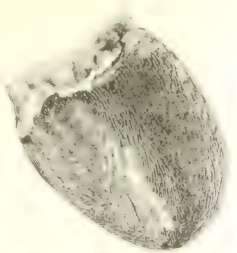


FIG. [illegible] tole (

It is difficult to follow accurately with the eye at one time the changes that take place in more than a single loop of intestine, but the camera records the progressive changes occurring in a number of loops, both above and below the one experimented upon.

The application of instantaneous photography may be further extended to the study of the contractions of the stomach, bladder, and diaphragm, and possibly to the study of the movements of the uterus in pregnant animals, and the lungs in artificial respiration.

The method is so easy and so accurate that I trust it may prove of permanent value in enlarging our knowledge of the action of drugs upon the cardiac and intestinal viscera, and possibly other organs.

CÆSAREAN SECTION ON ACCOUNT OF FIBROID TUMOR OF CERVIX UTERI.

By J. K. WEIST, M.D.,

RICHMOND, IND.

On September 6, 1885, I was summoned by Drs. J. B. and J. M. Clark to see Mrs. S——, and deliver her by abdominal section. The following history of the patient was furnished :

"Native of Indiana, aged forty-three ; seven years married ; never before pregnant ; had been for many years delicate and anæmic ; menstruation irregular until about one year before conception, then regular until November 4, 1884 ; no reappearance after this date, the usual signs of pregnancy being present. A fibroid tumor in the posterior wall of the cervix uteri was discovered two years ago ; this grew slowly until pregnancy occurred, then grew rapidly. It now fills the entire pelvis. On March 1, 1885, violent pain appeared in the right side of the pelvis, and continued for two months, half a grain of sulphate of morphia being required each twenty-four hours to make it bearable. Pain subsided at the end of two months, and the use of morphia was discontinued. General health rapidly improved, and she continued well until August 7th, when a free discharge of amniotic fluid occurred. This continued to flow moderately each day until the 14th, when the discharge was greater than at first. After this date the amount was small. Labor pains first appeared on the 28th, and continued—except when quieted by anodynes—until the present time.

"Dr. Clark was called on August 29th, and found the pelvis blocked up as described. The os could not be discovered. On September 5th a consultation was held, and the patient and her friends informed that natural delivery was impossible ; that abdominal section afforded the only chance of life to either mother or child. The desperate nature of the case was fully explained, and consent to the operation obtained."

I saw the patient at 10 o'clock A.M., September 6th. She was weak, yet in other respects in pretty fair condition. I found the entire pelvis filled with a hard and immovable growth, and could not reach the os. It being clearly impossible to do either laparo-elytrotomy or ovaro-hystorectomy, it was decided to make the Cæsarean section at once, all the medical gentlemen present concurring. Before the administration of ether, one drachm fluid extract of ergot was given.

Throughout the operation careful antiseptic precautions were taken. When the uterus was exposed, a very thin-walled cyst was found growing from it, pyriform in shape, about three inches long and two inches in diameter, attached to the peritoneal covering of the uterus, to the right of the middle line, at the middle and upper third of the organ, by a pedicle an inch long and one-fourth of an inch in diameter. A ligature was placed on the pedicle and the cyst removed. Its contents were semifluid and translucent, and greatly resembled thin jelly. At a corresponding point on the left side of the uterus another cyst, as large as an almond, and apparently of similar character to the larger one, was discovered. This was not disturbed. An incision five inches long was rapidly made through the uterine walls, the membranes ruptured, and the child found in the position of a first vertex presentation. The feet were seized, and a living male child, weighing about ten pounds, quickly delivered. Before the delivery of the child the hemorrhage from the divided uterus was much less than expected, but it was very alarming a little later, owing to imperfect contraction. No constriction of the neck of the uterus could be made because of the tumor in its walls. The cut edges were as firmly compressed as possible by the hands of myself and assistant, while hot sponges were placed inside the organ. During the few moments this state of affairs continued, ergotine was administered hypodermatically. Contractions soon came on, the placenta was detached and removed, after which there was but little bleeding. The uterine wound, probably owing to the influence of the tumor, gaped widely when the organ was contracted. The os was sought for from the inside of the uterus, and found as a narrow slit under the pubic arch. The growth was in the posterior wall of the cervix ; it filled the pelvis and was immovable. After the cavity of the uterus was cleansed, it was closed by the deep and superficial Sänger suture. It was not found necessary to dissect up the peritoneum, or to remove any section of the deeper structures, as the outer coat slid readily over the muscular layers, allowing it to be readily inverted, and welted into the uterine wound.

In cleansing the abdominal cavity the omentum was found contracted into a hard, nodular mass, adherent to the lower border of the right lobe of the liver. It was evidently in a state of malignant degeneration.

The wound in the abdominal walls was closed with silver sutures. Although for a few moments during the operation the loss of blood was alarming, the total loss was not very great.

At the conclusion of the operation the pulse was one hundred and ten, and of fair strength. Consciousness was quickly regained, and there was no appreciable shock. A small quantity of blood escaped through the vagina. The condition of the patient continued favorable for five hours, then severe pain in the epigastrium appeared ; this was followed by vomiting and great thirst ; pulse became weak and feeble, the vomiting continuing until near the end. She died twenty-four hours after the operation.

No post-mortem examination was made. The child, now four months old, is healthy.

The probably fatal delay of the operation in this case cannot be charged to the medical gentlemen in attendance. They were fully informed of the nature of the case, and of the necessity of early interference, and it was against their advice the operation was delayed.

Probably the full term of gestation had been reached when the membranes were ruptured—from the date of the last menstruation two hundred and seventy-six days. The first labor pain appeared at the end of two hundred

and ninety-seven days, and the operation was on the three hundred and sixth day, thirty days after the membranes were ruptured, and nine days after the pains of labor began.

A NEW APPARATUS FOR FRACTURE OF THE CLAVICLE.

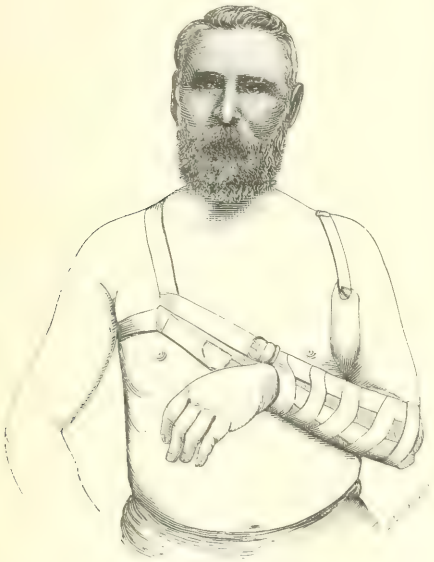
By JOHN C. MORGAN, M.D.,

PHILADELPHIA, PA.

The triple indications in fractures of the clavicle, viz., to hold the injured shoulder upward, outward, and backward, is fulfilled with various degrees of accuracy by the varied apparatus in use by surgeons; but the misfortune is, that with each, the amount of discomfort appears to be nearly proportional to this efficiency.

For instance, Fox's bandage is eminent in both respects, while adhesive plaster straps rival it in both.

Recently, the writer treated a prominent gentleman, with whom both forms of dressing were successively employed and found equally intolerable after a short time. The



plaster caused an eruption like that of croton oil, and the "bandage" soon became transformed into knotty ropes, cut the back, the axilla, and all other parts pressed upon, necessitating the interposition of pads, which constantly required renewal or readjustment. Moreover, during the hot weather, the sling excoriated the inner forearm, and this was only made tolerable by frequent bathing with alcohol. The many bitter complaints and demands for "something wider" than tapes, and less distressing than the now broken-down ring of cotton upon the sound shoulder and axilla, where the principal stress must be borne, led me to devise an apparatus which, while fulfilling perfectly every indication, appears to be entirely new in several important particulars. It is, in brief, a combination of bands of one and one-eighth inch suspender webbing, centring in a scalene triangle at the sound side, which completely takes the place of Fox's ring, and, unlike that, does not draw up under the head of the humerus at all, but lies flat upon the side of the chest by the base of the triangle, the short side applying itself to the scapula, at nearly a right angle with its spine, the third, or longest side, passing over and to the front of the shoulder, the whole enclosing this member somewhat as a horse's bridle accommodates the animal's ears, and quite as comfortably.[1]

The *stress of retention* is evenly balanced between the three angles aforesaid, by five bands of the same webbing, two in front, buckled to the inner and outer corners of the sling (of which and its construction more anon), and three behind, the uppermost going across the back to the top of the injured shoulder, to hold up the axillary pad, the fulcrum of the leverage of extension, and also drawing the shoulder backward, with the intervention of a buckle to regulate its length, ending in two narrow bands, diverging to be inserted into smaller buckles at the upper corners of the pad. The remaining two of the three back bands pass to the posterior end of the sling—*i.e.*, to the elbow, the upper and lower portions respectively—and are there buckled. The lower may seem superfluous, but it is the only tractor upon the posterior inferior *angle;* hence, it is necessary to a perfect *balance of force* in the whole triangle, whereby the latter is maintained in proper bearing position as the *counter-extending* agency, and at the same time kept comfortably applied, without slipping upward. Finally, the *sling* is made of the same webbing in open work, consisting of equidistant combined longitudinal and transverse strips. (The latter may, with suitable fitting, be semi-elastic.) Two non-elastic longitudinal ones pass, each in one piece, from the wrist back around the lower end of the humerus, returning to the wrist, one at the upper and one at the lower border of the forearm, as the foundation of the sling. About these, leaving the upper space open, are sewed the transverse strips. This forms a ventilated support, and when in place completes the means of leverage upon the fracture in extension. Four buckles (on the corners of the sling) receive the corresponding bands described above.

Napkins or strips of one thickness of linen torn from an old table-cloth interposed to absorb perspiration, and to keep the bands and pad clean, are very useful, but not indispensable.

[1] The phrase "scalene triangle" may need modification—as, when applied, it would, to some, appear to be practically almost a quadrangle; or, more exactly, perhaps, in the language of trigonometry, it is an "oblique spherical triangle." Straps taking the place of lines (without breadth), and applied to surfaces far from agreeing in any plane, the figure is not easy to describe mathematically. It is best compared with parallel lines one and one-eighth inch apart, drawn upon a man's coat, in the same directions, and it has the same contour as that particular portion of this garment. It is best, indeed, to fit it to the individual patient when making it up.

The practical working of this apparatus when applied to the patient left nothing to be desired, which, every surgeon knows, is saying a great deal. The extension, counter-extension, and retention, were entirely satisfactory, although using his hands constantly, and as to his personal comfort, it is enough to add that from the moment of its adjustment all complaint ceased; in short, he became thereby a happy man, and in due time was made free also, through the excellent completion of the cure. The simultaneous saving of time and trouble to the surgeon was not the least of the advantages obtained in this important case.

Clinical Department.

CONGENITAL MALFORMATION OF THE HANDS.

Dr. W. J. Middleton, of Steelton, Pa., reports the following case of congenital deformity, seen in the person of a negro, now twenty-one years of age. He writes: "Each hand has a thumb and three fingers, while the middle finger is absent. The only bones lacking in the right hand are the last two phalanges of the middle finger. The proximal phalanx exists, and is of normal size, but instead of presenting in a straight line, it inclines toward the ring finger and articulates with a second phalanx common to both of these proximal phalanges. Both bones are encased in one integumentary covering and form but one finger. The metacarpo-phalangeal articulation of the middle finger is very loose, and flexion leaves an interspace at the knuckle. The extremities of the two phalanges are not united into one bone, but are movable upon each other. The left hand lacks all the bones of the middle finger, and is cleft to the carpus. The two almost equal halves of the hand can be approximated and separated at will. The index finger of this hand has a veritable double joint at the knuckle. This joint has the usual forward flexion motion, and an almost equally perfect lateral flexion toward the ring finger. This motion results from the introduction of a sesamoid bone into the joint, a wedge-shaped bone larger on the thumb side of the joint. The finger is as nearly straight as is usual. The man says that his parents and brothers are perfectly formed, and he knows of no reason for the deformity. His hands, notwithstanding the malformation, are large and strong. His business is to carry pig iron from the cars at the Bessemer works."

A CASE OF ASCITES DEVELOPED IN UTERO.

Dr. F. M. Crandall, of this city, writes: "On December 9th Dr. W. Gill Wylie was called to attend a patient in labor. The head and shoulders of the child were born with comparative ease, but great difficulty was experienced in delivering the rest of the body, owing to the enormous size of the abdomen. This was found distended, very tense, the superficial veins prominent, and upon percussion flat at the sides and tympanitic above, with distinct fluctuation. There was marked cyanosis and embarrassment of respiration, evidently due to pressure. Clear amber fluid, which was not urine, was withdrawn by the hypodermic syringe. The child was large, and apparently sound in every other way. There was slight jaundice, but no more than is frequently seen in young infants. The mother seemed perfectly healthy. The father has consolidation at the apex of one lung, but is otherwise healthy. I saw the child at night, intending to aspirate, but as it was then more comfortable did not do so. I failed to pass a catheter, having none small enough, but on the following day a small catheter passed easily, and an ounce of normal urine was obtained. The urine was always passed naturally. On the following day there were three very large passages, black and tarry in appearance from the bowels, and at the same time the child had convulsions and rise of temperature. A few minute doses of calomel were followed by profuse natural movements and return of appetite. On the eighth day there was an attack of thrush, accompanied by diarrhœa and a papular eruption on the chest and extremities. It yielded easily to treatment, and both the thrush and eruption had disappeared in a week.

"The abdomen gradually became less distended and tense, the veins less prominent, and by the fourteenth day the fluid had nearly disappeared. During the first week the child had rapidly lost flesh, and became pale and pinched in appearance. This look had now passed away, and the child was growing and making rapid improvement when it was seized with capillary bronchitis, from which it died in five days. There was at that time no evidence of fluid. The abdomen was normal in appearance and size. No autopsy could be obtained."

A TOOTH GROWING IN THE NOSE.

Dr. E. Hanson Griffin, of New York City, reports the following case: "Patient, G. I——, aged thirty-two, applied to the Bellevue Throat Clinic, complaining of a sore throat and a pain in the back of the head of two days' duration.

"An examination of his throat showed that there was a cleft of both the soft and hard palate. In examining the upper gum I noticed the root of the second incisor tooth in the tissue, while an examination of the nose showed the tooth in a perfect state of development projecting from the floor of the nostril upward into the nasal cavity. He said the tooth had been there for years and gave him no trouble. He never remembered suffering any particular pain when it was growing, in fact did not know anything was the matter with his nose till one day while putting his finger into it he noticed something hard, and looking into a mirror found it to be a tooth. As it gave him no trouble he did not apply to a physician. He does not think the tooth has grown any of late years. He was a twin, but his sister's throat was in a perfect condition, and her nose free from any defect. The patient was opposed to any operation for the removal of the tooth, and as his sore throat was of a trivial character and not dependent upon his trouble, I did not urge a destruction of one of nature's whims."

DISPLACEMENT OF THE LARYNX CAUSED BY GOITRE.

Dr. J. W. Gleitsmann, of this city, presented the following case at a meeting of the Laryngological Section of the New York Academy of Medicine, January 22, 1886: Patient, male, fifty-two years of age, had a hard, fibrous goitre, causing displacement of the larynx to the right side and rotation on its vertical and antero-posterior axes. The upper part of the left thyroid plate was nearer the median line than the lower left part of the larynx, which was almost one inch removed from it. The whole larynx was also so turned on its vertical axis that its anterior part with the junction of the thyroid plates looked toward the median line, while the posterior part with the arytenoid cartilages was deflected outward.

The laryngoscope showed diagonal position of the vocal cords and glottis, running obliquely from left to right, and being located altogether on the right side of the throat. The cords approximated well, which fact accounted for the comparative clearness of the patient's voice. The lower part of the larynx being pushed further out, the left arytenoid cartilage had to make excessive movements to meet its fellow on the opposite side. The deviation of the larynx from the vertical line explained the fact that the right half of the larynx, especially the right cord, appeared to be in a somewhat higher plane than the left cord.

THE DECLINE OF IRIDECTOMY.

Dr. C. E. Nelson, of New York, writes: "A news item, with this heading, appeared in The Medical Record of February 13th. Frequent changes are made in operations on the eye, notably in that of cataract. In the quotation from the *Medical Press* emphatic language is used regarding the innovation of iridectomy, as well as other medical fashions. But I will simply give a retrospect of the history of iridectomy. Before 1861, von Graefe, son, announced the *rationale* to be the relief of tension of the globe, as the iris being lessened, from shrinking back, its secreting surface poured out less aqueous humor. Bowman considered that iridectomy permitted a more direct communication to be opened between the aqueous and vitreous regions, allowing the morbid fluidity to come forward. Hancock, of Charing Cross Hospital, London, stated that glaucoma is due to spasm of the ciliary muscle; he therefore divided it; but Bowman dissected glaucomatous eyes, where there was completele atrophy of that muscle. The old surgeons, Antonius, Nucks, Johns, and Meckren, used to tap the globe; also Wardrop, in 1813. In our own day, paracentesis of the sclerotic has been advocated by Desmarres and Hancock.

"According to Bowman, glaucoma depends on inflammation or congestion of the choroid, the ocular pressure being a secondary condition. Von Graefe's operation is only calculated to remove the effect of the disease; it has no power whatever over the original cause of it—the inflammation (Nunnelly). As to the operation, Nunnelly entirely refutes von Graefe's statements, and substitutes an operation of his own, cutting through the constricting band, or junction of the different coats with the cornea. This operation is superior to Hancock's. All these operations are merely a form of paracentesis, with this difference, that ordinary paracentesis through the sclerotic does not relieve.

"Magni gave a theory opposed to that of Graefe. A subsequent theory was that instead of there being increased tension caused by increased production of fluids in the globe (from irritation of the ciliary nervous system), the glaucomatous tension was caused by an increased density of the sclerotic, which prevented exosmosis; therefore the treatment consisted of making a simple incision through the sclera. Wecker used to insert a fine gold wire—also in cases of separation of the retina by effusion.

"Galvanism has been recommended for glaucoma."

DISLOCATION OF THE UNGUAL PHALANX OF THE THUMB AND OTHER INJURIES.

Dr. Horace E. Marvin, of Brighton, England, writes: "Reading in The Medical Record of January 16, 1886, a case of 'Dislocation of the Ungual Phalanx of the Thumb,' I am led to refer to a somewhat similar one which came under my care but a few days ago. E. B——, about fifty-five years of age, while intoxicated, fell down a long flight of stairs. I was summoned just after the accident, and upon examination found a compound dislocation of the left thumb. Both articular surfaces of the joint were exposed, the ungual phalanx being bent backward at a right angle with the proximal phalanx, and the wound extended quite across the palmar surface of the joint. The dislocation was easily reduced *secundum artem*, three sutures were introduced, and the thumb was put up in an extemporized pasteboard splint. The patient had complained only of his thumb, but when this was attended to he said he thought the right elbow was not all right. Upon examination it proved to be a multiple, probably T, fracture of the lower end of the humerus. While examining this I noticed a deformity of the right shoulder, which proved to be a dislocation of the head of the humerus into the axilla. Under ether I reduced the dislocation of the shoulder and confirmed the diagnosis of the fracture."

Progress of Medical Science.

Jejunostomy.—At a recent meeting of the London Clinical Society (*The Lancet*, December 5, 1885) Mr. Golding-Bird related a case of jejunostomy. The case was that of a man, aged forty-six, who had had symptoms of pyloric obstruction for ten months. When admitted into Guy's Hospital a tumor could be felt at the seat of the pylorus, and the man's general condition was one of extreme emaciation, through inability to retain the food he took, and his voluntarily abstaining from eating on account of the pain he suffered. After three weeks' treatment under Dr. Carrington by drugs and washing the stomach out, he passed into Mr. Golding-Bird's hands, and when all the risks had been explained to the patient, and all methods of palliation had failed to improve his condition, arrangements were made to explore the diseased parts and remove them if expedient. Mr. Golding-Bird, therefore, on October 25, 1885, cut down on the pylorus with a view to performing pylorectomy, following the lines laid down by Billroth; but, finding the tumor adherent to the liver, he determined to go no further with the radical operation, but to convert it at once into a palliative one of opening the jejunum—in other words, of performing jejunostomy. Having seized the jejunum two inches from the duodenum, it was held up on a pair of tongue-forceps, while the wound in the parietes was united; to the lower or right end of this wound was the jejunum now stitched by interrupted sutures. The patient suffered in no way as the result of the operation. He was fed partly by the rectum, partly by the mouth, until the third day, when the bowel was opened and food administered solely through the fistula. It was observed that as long as the meal amounted to a pint or nearly so, the patient each time he was fed had a severe attack of indigestion, but that this ceased when the meal did not exceed ten ounces. On this the author founded the suggestion that some cases of indigestion were due to the pylorus allowing too free passage of chyme, rather than to disturbance of the gastric or pancreatic secretions. Everything went on perfectly well till the ninth day, the patient gaining flesh; but on that day, through an error in feeding him, some food passed into the peritoneum, and he died in twelve hours. The post-mortem inspection showed such adhesion to and infiltration of the liver of the cancerous pylorus that pylorectomy could not have been performed. Except the narrow track made by the probe, and along which the food passed into the peritoneum, the adhesions of bowel and parietes were perfect. The author then reviewed the operation of pylorectomy, speaking in favor of it in suitable cases, and the operation of gastro-duodenostomy, as performed by Wölfler, and pointed out the great drawback in this operation, that the stomach is not relieved of its physiological duties at all, the pylorus not being required to act. For the operation of jejunostomy, as he termed the one that he detailed, he claimed that, while it possessed the same disadvantage as gastrostomy, in that the patient had to be fed through the fistula, it was otherwise the best palliative operation for pyloric cancer, inviting less risk than gastro-enterostomy and requiring less interference, in its performance, with the other viscera. By duodenal digestion, he also pointed out, full nourishment could be assured and there was, for physical reasons, less chance of regurgitation of food than after gastrostomy, regurgitation in these cases being a serious drawback to that operation in œsophageal constriction.

Double Congenital Displacement of the Hip: Description of a Case with Treatment Resulting in a Cure.—Dr. Buckminster Brown, of Boston, has placed on record a remarkable case, and for this reason it is worthy of notice in these columns. Seven or eight pages are devoted to the history of the mechanical therapeutics of this intractable deformity. The author quotes

from standard authorities enough to establish the recognized incurability of the ailment. He gives sufficient reference to the few reported cures, and shows how worthless much of the advice and many of the forms of apparatus are, when submitted to a critical investigation. He has not omitted a reference to coxectomy as practised by Margary, E. Rose, and C. Reyher. All surgeons have recognized the obstacles to retaining a displaced head in a shallow or imperfectly developed acetabulum. All have felt that if a new acetabulum could be formed, in place of the one impaired or completely deficient, a cure might result. Hence the attempt on the part of surgeons who possessed the character of boldness to make, by operative interference, the cavity so much desired. The results of these operations have not been sufficiently brilliant to encourage an extensive resort to the practice. The case here described is a well-authenticated instance of the entire formation of new acetabula in the places selected for them. In this respect it probably is unique. The profession, therefore, is indebted to Dr. Brown for recording a case with such candor and with such an admirable result. His patient was a girl, four years of age, in whom the deformity was well marked, and his description is sufficiently graphic to enable one to make the diagnosis. The treatment was begun December 30, 1882, and the first stage of treatment extended to January 6, 1883, during which time warm poultices were employed in order to relax the muscles. Direct extension was now made, the object being to tire out and stretch the pelvic muscles. After ten or twelve days there was sufficient relaxation to allow easy manipulation of the bones, and they were placed in natural position each morning. The tendency to slip, however, was still very great. By the middle of February this tendency had greatly diminished. Another stage was now begun, the object being to excavate a socket by absorption; the limbs were strongly everted, with the thighs flexed to nearly right angles to the body. It was necessary to secure the limbs in this position, but it could be borne for only two or three hours in the course of the day. At no time was the extension remitted, and the last time a displacement of either hip occurred was March 28, 1883. It was not until July 20th that any attempt was made to test the result, when there was found firm resistance in each direction, thus demonstrating the perfection of the newly formed sockets. In January, 1884, for the first time in thirteen months, the patient sat up in bed. The further progress of the case was exceedingly slow, and various devices were resorted to in order that no violence should occur to the reparative processes. On May 25, 1885, "the child's walk is normal and she enjoys walking; she steps with natural firmness and vigor. Like other children she takes a special pleasure in running." The brochure is well illustrated, with exact reproductions of photographs representing the different stages of treatment, the apparatus employed, and the different positions of the limbs during the course of treatment. It is impossible to give the details of treatment in a notice of this kind, and hence we must refer those interested to the little volume itself. A perusal of the same will call forth admiration for the persistence with which the surgeon carried out the treatment under such discouraging circumstances.

Contributions to the Physiology and Pathology of Digestion.—Drs. Ewald and Boas have recently endeavored to throw some new light on the physiology and pathology of digestion (*The Lancet*, December 5, 1885). The investigations of Leube, Riegel, Ewald, and others, on the secretory activities of the gastric glands leave much to be desired. Indeed, in the present state of knowledge, it does not seem clear that any certain indications can be drawn from the chemical and physical condition of water that has been used to wash out the stomach—a method that has usually been followed in physiological investigations on man. The quantities of pepsin and free hydrochloric acid thus obtained vary so much, even in physiological circumstances, that a precise application of the results to the determination of pathological states is impossible. Again, Leube thought the secretory activity of the gastric glands might be inferred from the duration of gastric digestion, but experiments do not appear to support this view, for different observers have given different times as the duration of normal digestion. Then the influence of the motor and absorbent functions on the gastric secretions is altogether conjectural. In carrying out some fresh observations, Ewald and Boas have made use of some cases in the *Frauen-Siechen-Anstalt* in Berlin. One of the cases was that of a hysterical girl, aged twenty, who ever since the age of fourteen had been subject to vomiting, which regularly followed every meal. The particular time at which the emesis occurred appeared to vary proportionally to the kind of food ingested. If fluids were given, vomiting came on immediately; whereas if solids were administered, the stomach was not emptied for from two to four hours. As the result of several hundred observations on this girl, Ewald and Boas found that during fasting the contents of the stomach were free from the remains of food, as a rule neutral, and contained neither free hydrochloric acid, lactic acids, nor peptones. Schultz and Leube have stated that during fasting the reaction of fluid withdrawn from the stomach is strongly acid. According to the authors, it would appear that there is no foundation for the belief that lactic acid is necessary to the construction of hydrochloric acid. The main facts that have been elicited by Ewald and Boas are, first, that lactic acid tends to disappear as digestion goes on; and, secondly, that its disappearance is the more rapid the more active the digestive process is, but is also largely dependent on the kind of food. The earliest appearance of free hydrochloric acid and peptone is the third question that has been investigated. The experiments show that the process of peptonization begins almost immediately after the ingestion of food, and that in a mixed diet the process is directed at first rather by the lactic than by free hydrochloric acid. The curves of peptonization and the formation of hydrochloric acid go precisely together, attaining their summits at the same time, and falling synchronously. The summit of the curves does not coincide with the termination of digestion, but corresponds with the period at which the digestive activity is at its height; so that the formation of hydrochloric acid and peptonization attain their maximum some time before the disappearance of the contents of the stomach. The final question to which the authors address themselves is the part played by fat in gastric digestion. As a rule fat hinders the activity of gastric digestion. Fat remains a long time in the stomach, and no doubt leads to the formation of fatty acids, which cannot be without influence on the physiological processes. It had been found that on a pure white-bread diet, after fasting, the lactic acid could be detected for sixty minutes, after which time only hydrochloric acid could be found. But when fat or butter was also added, the duration of the digestive process was increased to two and three hours, according to the proportion of fat. In these experiments it was also found that hydrochloric acid was present in but small quantity, while lactic acids existed in abundance. To the deficiency of effective hydrochloric acid Ewald and Boas attribute the prolongation of digestion. This series of experiments also confirms a point already alluded to, that when the digestion is prolonged the lactic acids are slow to disappear. The chief conclusion to be drawn from these investigations is that the prolongation of digestion is the most certain sign of impairment in the process. This prolongation may be brought about as the result of mechanical disturbances and chemical alterations. The therapeutic indications to be gained from these considerations would appear to be the removal of all those influences which prevent the proper locomotion of the stomach, and the due performance of its chemical work, or that hinder its absorbent powers in any way.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 13, 1886.

RECENT PROGRESS IN HOSPITAL CONSTRUCTION.

THE hospital is the product of an advanced and Christian civilization, and the good that has been wrought through its agency is incalculable. We are realizing now, however, that hospitals in the past must often have been most bungling instruments in relieving disease and suffering. In ninety years, for example (1741 to 1827), the proportion of cures to deaths in St. Bartholomew's Hospital increased fivefold; and even in the present century the death-rate in Bellevue Hospital was for forty years twenty per cent. on admissions, instead of the present number, ten. It was partly owing to the imperfect construction and ventilation of hospitals that the death-rate for all amputations used to be nearly forty per cent., while now it has been reduced more than one-half. There is plenty of evidence now to show how imperfect in construction and administration our hospitals used to be, and, to a large extent, still are, undoubtedly. The victims of bad hospitals are greater in number than those of war and pestilence.

For many years hospitals have been built according to conventional methods, and with no particular reference to sanitary laws. It is only in recent times that the laws of hospital building are becoming known, formulated, and followed. The main principle in modern hospital construction is that of the one- or two-storied pavilion, water-closets and administration offices being separate from the wards. Dr. A. C. Heffinger, U.S.N., has recently given (*Boston Medical and Surgical Journal*, February 4, 1886) an interesting account of what he believes is a still further step in advance, viz., the circular pavilion ward.

Dr. Heffinger says: "The great advantages of circular structures, especially when surmounted by domes, seem to have been first discovered by Dr. McKenna, a Scotchman, who happened to be in South America about forty years ago during one of the many revolutions which have repeatedly convulsed the petty republics of that continent, and who had the care of a number of wounded. The patients were treated in convent rooms, which were always rectangular, and in convent churches, which were always in the form of domed circles. Those patients treated in the churches did so much better, indeed marvellously better, than those cared for in the rooms, that he was struck by the difference, and induced to make a close study of the matter. This clever Scotchman soon became convinced that circular structures with domed ceilings were far superior to any other tried form for housing the sick.

"Sir Andrew Clark, who recalled the views of Dr. McKenna before the Hospital Association of London in December, 1884, also related at that time how he had accidentally discovered the automatic ventilation characteristic of the domed circle, while inspecting the grand domed circular tomb at Delhi, in hot, calm weather. He inadvertently let fall from his card-case a small slip of tissue-paper, which, to his amazement, instead of falling slowly to the floor was steadily wafted upward to the centre of the dome. Afterward he made repeated experiments of the same nature in various parts of the circular domed temple at Calcutta, and always with the same result. It is quite evident that there are natural air-currents directed upward from all parts of a room thus shaped, though the governing philosophy is by no means clear.

"The circular ward was also originated independently by M. Baeckelmans, of Antwerp, in 1873, and Professor John Marshall, of London, in 1878."

Dr. Heffinger states that he also independently conceived the idea that circular wards were the best. At present the Antwerp Civil Hospital and the Miller Memorial Hospital are the only completed types of this form of hospital. There are, however, several hospitals in France built upon the *Système Pollet.* These are one-storied pavilions, with arched Gothic roof, and have, perhaps, some of the same capacity for natural ventilation.

It saves lives to build hospitals according to the best sanitary principles. Still it is often impossible from lack of money to do this; and it cannot be denied that by scrupulous cleanliness almost as good results can be gotten by the surgeon, at least in old-fashioned hospitals, as in the most scientifically constructed edifices.

In this connection we may add a notice of a most ingenious field hospital recently invented by Mr. William M. Ducker, of Brooklyn. It may be remembered that about a year ago international competition was solicited, through a prize offered by the Empress of Germany for the best design of a portable field hospital useful for the work of the Red Cross Society. The exhibition of the inventions called forth by this imperial order occurred at Antwerp, Belgium, not long since, and a silver medal was awarded to Mr. Ducker, who, in addition, has been honored with a message from the Emperor, congratulating him upon the excellence of his invention.

In an account of it given in *Harper's Weekly*, it is said:

"When it is borne in mind that this structure, which is entirely weather-proof, can be erected without the driving of a single nail; that its weight when taken apart and packed for transportation is only about two thousand five hundred pounds; that its cost, completely furnished, is from two hundred to two hundred and fifty dollars; and that two men can easily erect it in a little more than an hour's time—its points of superiority over the hospital tents hitherto used in the field will begin to become apparent."

We have only space for the following facts regarding its construction: "The main structure is thirty-four feet long and seventeen feet wide, the height from the floor to the ridge-pole being ten feet three inches. The whole

is built in sections which are so arranged with keys and slots as to lock into one another. The sides of the structure consist of six double sections, which may be roughly described as strong wooden double trays."

THE GALVANO-CAUTERY IN DIPHTHERIA.

As startlingly severe as this means of therapy may seem, it yet has been tried by one or two bold physicians on the Continent, and, as was to be expected, they are enthusiastic in its favor. It appears to have been used nearly thirty years ago, but we can easily fancy that in spite of reported cures it was not tolerated and speedily fell into disuse. Nor do we believe that it will ever become, with parents at least, a popular remedy in the treatment of our most powerful foe, diphtheria. They will look upon it just as they would regard the actual cautery—as a "red-hot iron"—much as they now regard tracheotomy, as "cutting the child's throat."

The only definite information concerning this measure is by Tedeschi, of Trieste, and Bloebaum, of Coblenz. The latter had used this agent in similar pathological conditions in ophthalmological practice. He assured himself that the galvano-cautery (the wire loop) does not produce inflammation, but is an antiseptic, leaving the necrosed parts harmless and powerfully stimulating the underlying tissues to healthy growth. He regards it as the only true and certain parasiticide.

Tedeschi gives a well-written account of the actual application of this method of cure. The pain inflicted is slight. A cocaine spray has not been deemed necessary. When the pseudo-membrane is touched with the heated wire loop it curls up, finally sloughs off, and the ulcerated surface left does not reproduce the patch. If the whole exudate is removed in this way, the process does not extend beyond the limits of its former margins. After the above procedure, the fever, œdema, and glandular swelling all disappear. The period of the coming away of the eschar varies from the eighth to the eighteenth day. The immediate after-treatment is limited to swallowing chipped ice. Later, benefit may be derived from the customary steam and lime-water sprays and gargles.

The great advantage claimed for this method over the use of chemicals is in its perfect localization. Any solutions to be of great power must be so concentrated as to irritate surrounding tissues. Toleration by the latter necessitates a solution so weak as to be practically useless. A specific ulcer is by the cautery converted into a simple one—so say the advocates of the new method.

It will at once be seen that this idea premises a view of the nature of diphtheria which is still under discussion, and by many competent minds rejected, namely, that the disease is primarily a local one, and that constitutional symptoms arise from septic absorption through the lymphatic channels. Whether this be true or not, we know that many cases present themselves in actual practice where there can be no doubt as to the diagnosis, and yet where the throat does not present any exudation—in other words, where there is no indication for the use of the cautery. We do not think that under any circumstances the cautery method of treatment will become popular in American medical practice. It must be looked upon as a therapeutic curiosity, and rather a forbidding one at that.

PHYSIOLOGICAL EXPERIMENT AND ITS RELATION TO THERAPEUTICS.

It is gratifying to observe the large amount of really practical work which physiologists have accomplished during the past four or five years in a branch of research which offers constant temptations for wide theoretical digressions, and for the accumulation of endless data which can be turned to no practical account. Especially prominent in their value as a contribution to medical science are the classical experiments of Matthew Hay upon the action of saline cathartics, and the experiments of Professor Martin upon the isolated mammalian heart, which was kept beating for many hours while it was made to exhibit the effects of alterations in both venous and arterial tension upon the work of the heart.

The admirable work of Lauder Brunton upon therapeutics gives the most instructive summary of recent practical physiology, and is in itself an irresistible argument for the continuance of properly conducted vivisections. A valuable and interesting contribution to the methods of physiological research is briefly outlined in another column by its discoverer. It is an ingenious application of the process of instantaneous photography to the study of the action of drugs upon the living heart and intestines, which possesses the advantage of reducing the errors of personal observation to a minimum, besides affording a graphic method of enlivening many facts of materia medica which prove so difficult for students to acquire. We have had an opportunity of personally examining several hundred of the photographs, as well as of seeing the negatives enlarged by a stereopticon, and we are convinced that this method of demonstration could be made of great value for instructors in physiology and therapeutics.

PYROGALLIC ACID IN THE TREATMENT OF SKIN DISEASES.

Pyrogallic acid is just now the vogue among many dermatologists, and there is considerable evidence as to its especial utility in certain skin diseases. Dr. Charles W. Allen, of this city, has given a very complete account of the uses of this drug in an article in *The Journal of Cutaneous and Venereal Diseases* for January, 1886. Introduced by Jarisch, of Vienna, about seven years ago, it has been extensively used since then by Kaposi and Neumann, of that city; by Schwimmer, of Buda-Pesth; Besnier, of Paris, and others, including several physicians in this city.

The diseases in which it has been tried have been chiefly psoriasis, lupus, epithelioma, and chancroid, but there seems to be no doubt that it is against lupus that pyrogallic acid acts best. The method of using it here, as described by Schwimmer, is as follows:

"Vaseline is first applied for several days, or as long as necessary to remove all secondary morbid products, scales, secretions, and dirt, a ten-per cent. pyrogallic ointment is then applied during from four to seven days, being renewed two or three times daily. Vaseline is now to be applied again for one day to remove all of the acid. The entire suppurating surface is now to be covered with mercurial plaster, under which healing takes place in from ten days to two weeks. This process may be gone through with several times until no more tubercles appear. Professor Schwimmer says the

treatment of a case seldom exceeds three or four months. A speedier and much better resolution of the most advanced and wide-spreading lesions are found to take place under this combined plan of treatment than could be accomplished by the combined treatment of scarification and the thermo-cautery."

Occasionally some toxics effects are observed from the use of pyrogallic acid, but this is rare and only occurs when it is very extensively applied. It has not supplanted the use of chrysophanic acid in the treatment of psoriasis.

THE TREATMENT OF CHRONIC GONORRHŒA WITH CANNELLATED SOUNDS.

DR. LEOPOLD CASPER, of Berlin, states that he has succeeded in curing thirty cases of chronic gonorrhœa with the "cannellated sound." Fourteen of these had already been treated for over a year and a half, and six for over a year by various other measures. Despite the assurances of some specialists to the contrary, there is often nothing more difficult to cure than a long-standing case of gonorrhœa. The use of sounds and urethrotomes, of deep injections and cauterizations, of salves and medicated bougies, will all fail at times, while the patient is liable to become the prey of quacks or to relapse into hypochondriasis.

Dr. Casper starts out with about the same confidence in his new cure which is expressed by all who devise a new therapeutic measure for the relief of urethral and sexual difficulties. There is something in the nature of this department of medicine which makes its therapeutics untrustworthy, and we are very much disposed to distrust the assertions of Dr. Casper. In the first place, it is the general experience of those who make a specialty of treating mucous membranes, in whatever part of the body, that medicated cerates, ointments, etc., are not very efficient agents. Despite much pushing, the use of soluble bougies, for example, in the treatment of vaginal, uterine, urethral, and nasal troubles has not attained any great foothold. It is true, however, that the application by sound of Unna's salve in chronic gonorrhœa has been occasionally effective, and Casper's method is rational in that it combines the use of mechanical pressure and chemical action upon the diseased part. His cannellated sounds are of the ordinary shape, with six grooves, one and a half millimetre deep, running from the handle to within five centimetres of the point. These grooves are filled with a mass which is solid at the temperature of the room, but melts at the temperature of the body. The formula given is as follows:

℞. Olei theobrom.	100.0
Ceræ. flav.	2.0–5.0
Argenti nitrat.	1.0
Balsam. Peruvian.	2.0

In the beginning a three per cent. resorcin ointment is sometimes used, but the silver is believed to be better in obstinate cases. The sounds used are of "neusilber," and no chemical action occurs through the presence of the nitrate.

If the patient has a stricture of small calibre it is dilated with bougies up to No. 18 Charrière, and then the cannellated sounds are used, increasing their size up to No. 23. The sound should be allowed to remain in the urethra for from a few minutes to half an hour, the longer the better, provided it is not too painful to the patient. An average of about ten applications was found necessary to cure the cases.

Dr. Casper considers it important to locate the gonorrhœa, and gives some indications for diagnosticating between an anterior and a posterior gonorrhœa. Most of his cases were situated at the junction of the bulbous and membranous parts of the urethra. Of 100 callous strictures 70 were in this location, 20 in the fossa navicularis, and 10 in the remaining portion of the pars spongiosa. When the disease is limited it is not necessary to fill up the grooves of the sound their whole length with the medicated ointment.

SYPHILIS AND VIRGINIA CIGARETTES.

CERTAIN Southern tobacco firms have undertaken to advertise their wares by distributing photographs of the young women in their employ. The scheme is ingenious, and we doubt not commercially advantageous to photographers, cigarette-makers, and the cigarette girls. The majority of the pictures in question are of young women posed in positions calculated largely for the display of their lower limbs and neatly striped hosiery. With the morality of the policy which aims to sell cigarettes by exhibiting the legs of the female employees we have nothing to do. But it should merely, from a business point of view, eventually turn out to be a bad one. For only one thing can be thought of the women who consent to have themselves thus photographed. The Virginia firms are in effect informing the people, their customers, that some loose women are concerned in making their cigarettes. Now such women are constantly liable to have syphilis, and while syphilitic to roll cigarettes. It would be quite possible for infection to be sent with the articles upon which they work. It is well known that syphilitic cigar-makers have infected their cigars, and the same thing may happen with cigarettes. At any rate the intelligent customer will hardly care to purchase cigarettes made by those whom he may reasonably think are prostitutes.

BEER AS A CAUSE OF DISEASE.

THE State Board of Health has had an analysis made of various samples of beer, four hundred and seventy-six in all. The State analyst, Dr. F. E. Engelhardt, who made the examinations, found substitutes for malt in about one-fourth of the samples. He found no specially deleterious substances in the beer from the breweries, but did find glucose and bicarbonate of soda. Beer from retail dealers is more likely, it is said, to be adulterated, the substances used being burnt sugar, quassia, cocculus indicus, etc.

It was also found that the sanitary condition of some breweries was very bad. A law was recommended providing that beer shall contain only hops and malt, or their constituents, and that the breweries and beer itself shall be constantly subject to State inspection.

Some three years ago the *Mail and Express* collected a large amount of testimony from medical men as to the deleterious effects of ingredients of beer, and the subject has been again revived in its columns.

The facts alleged against beer are that its consumption is enormously and alarmingly increasing; that it is often adulterated with injurious matters, and that its excessive consumption causes disease of the kidney, fatty liver, and "biliousness," fatty degeneration of the heart, and other degenerative changes.

It is estimated that the total amount of malt liquors brewed annually in this country and Europe is three billion gallons, of which six hundred million are brewed in the United States. The average amount consumed annually per capita, in our country, is now about eleven gallons, while forty years ago it was only one gallon. The annual increase in the production of beer is from six to seven million gallons. The number of breweries is now two thousand two hundred and thirty.

The very rapid increase in the production and consumption of beer is beyond a doubt, but it is not safe to found any alarmist statements on this ground, for it appears from figures given by Mr. Samuel G. Child, of Boston, that the total amount of alcohol consumed per capita in the United States is not increasing, but rather the contrary. Thus, assuming that the amount of pure alcohol in spirits, wine, and beer is fifty, eight, and five per cent. respectively, the table which he gives is as follows:

GALLONS ALCOHOL CONSUMED PER CAPITA.

	Distilled spirits of fifty per cent.	Wine at eight per cent.	Beer at five per cent.	
1840	1.200	.023	.069	1.[illegible]
1850	1.115	.022	.070	1.[illegible]
1860	1.430	.028	.[illegible]	1.620
1870	1.[illegible]	.026	.[illegible]	1.[illegible]
1880	.620	.017	.[illegible]	1.[illegible]
1881-82-83-84 ..	.[illegible]	.[illegible]	.[illegible]	1.[illegible]

As for adulterations, the additions of glucose and soda are comparatively harmless. The other additions, of which long lists are given, are found by the State chemist in small amounts or not at all. By far the most serious adulteration, and practically the only one, is that of alcohol. The exact extent of this adulteration cannot yet be determined, but that it is made there is little doubt. Fusel-oil and cheap corn alcohols have been used; but lately, as we are informed on good authority, methylic or wood spirits have been employed. In lager-beer the alcohol amount is small, and is much less often fortified with impure spirits.

The injurious effects of beer come on slowly and insidiously, if at all. They are very marked in persons who drink continuously and excessively. The excessive ingestion of fluid causes a plethora, then hypertrophy of the heart and fatty degeneration of its muscle. In Munich the normal male heart, for example, weighs more than elsewhere, and it is often found to be fatty.

The charge that the habit of beer-drinking causes Bright's disease or serious liver disease is not very strongly suppported; still, it has some facts in its favor. Since 1870 the consumption of beer in this country has doubled. In New York City the ratio of the deaths from Bright's disease has changed from 3.40 per cent., on the total annual deaths in 1874, to 5.40 per cent. of the total deaths in 1884. Here is apparently a very striking increase; still, of course, no positive deductions can be drawn from such data alone.

News of the Week.

REMARKABLE FECUNDITY.—Dr. C. L. Fletcher, of Wing's Station, N. Y., writes: "In the medical items of THE MEDICAL RECORD of February 27th mention is made of two women presenting at Professor Parvin's clinic who had borne respectively eighteen and sixteen children. A woman residing in this town has given birth to twenty-five children. She is hardly past the prime of life, and is now in good health, having recently recovered from an attack of scarlet fever. When the writer was in practice in Northern Vermont he often had occasion to prescribe for the different members of a family in which the mother had given birth to twenty-five children, having three pairs of twins in the crib at one time. The same woman had two sisters who had borne respectively twenty-two and eighteen children, making a total of sixty-five from the three sisters. It is needless to say that all the families are poor in the financial sense."

DR. GASPAR GRISWOLD.—The medical community was greatly shocked to learn of the sudden death, on March 4th, from peritonitis, of Dr. Gaspar Griswold. Dr. Griswold was only 29 years of age, but he had already given promise of a brilliant career. He was born in this city in 1857. He graduated from Columbia College in 1876. While in college he was prominent as an athlete, and was a member of the famous crew which in 1874 won the intercollegiate regatta at Saratoga. In the course of his professional studies he served a term as house physician at Bellevue Hospital. Subsequently he went to London, where he took the degree of Fellow of the Royal College of Surgeons—an unusual honor for a young American. On his return to this country he became associated professionally with Dr. Fordyce Barker. He also became Demonstrator of Anatomy at Bellevue Hospital College, and held that position at the time of his death. He frequently contributed articles of value to the medical journals. Dr. Griswold was socially a most agreeable man, and was very popular with all who knew him. He left a wife, but no children.

THE DEATH OF DR. GEORGE MCINTOSH MACLEAN of Princeton, N. J., in his eightieth year, is announced.

THE BALTIMORE MEDICAL COLLEGE held its Annual Commencement on March 4th, graduating a class of sixteen.

THE NEW YORK POLYCLINIC.—The report of the Secretary at the annual meeting of the Directors and Faculty of the New York Polyclinic, held at the College Building on January 28, 1886, showed an attendance upon the clinics in that institution, since the opening, on November 7, 1882, of seven hundred and nine physicians. Of this number, one hundred and fifty-six had taken out the general ticket, which admits the holder to the lectures in all the departments taught at the school.

The ratio of attendance upon the various departments is shown in the following list of tickets sold since November, 1882, up to January 28, 1886: Gynecology, 461; surgery, 412; medicine, 313; throat, nose, and ear, 300; children, 273; eye, 250; skin. 234; mind, and nervous system, 207; physiological chemistry, 173;

obstetrics, 163; pathology (laboratory only recently opened), 15. Total, 2,801. The attendance for the present session is in excess of any previous term.

Intermittent Uterine Contractions.—Dr. E. H. Grandin, of New York, writes: "In the issue of The Record for February 27th, you quote from a letter from Dr. Hall of Ohio to the effect that I was mistaken in saying that 'an intermittent rhythmical contraction of the uterus, as a positive sign of pregnancy, is referred to by only one authority (Lusk), and by him very briefly.' And then follows reference to Mr. Tait as being further authority. Had your correspondent read the abstract of my paper in your journal carefully, or had he waited till he had seen the paper in its entirety, he would not have himself fallen into the error of charging me with making any such statement as the above. Every writer on obstetrics refers to the value of intermittent uterine contractions in the diagnosis of pregnancy. The point I endeavored to make, and which is clearly made in my paper, if not in the abstract referred to, was simply that this sign was of peculiar value in the *differential* diagnosis between *two* varieties of pregnancy—the uterine and the abdominal—and that in this connection the sign is not referred to as of value by any obstetrical writer except Lusk. It would appear, therefore, that after all, Dr. Grandin was *not* mistaken.

"N. B.—This sign is particularly of value in differential diagnosis, because, in case of abdominal pregnancy, all other signs of pregnancy may be present, and this one alone being absent, the differential diagnosis is at once made."

The Origin of the Montreal Epidemic of Small-pox.—The sub-committee appointed by the Civic Health Board to inquire into the origin of the late small-pox epidemic have submitted their report. From this we learn that previous to the beginning of 1885 there had been no small-pox in Montreal for several years. There is some disagreement as to the origin of the epidemic, but it seems probable that the disease was brought to Montreal from Chicago by an infected Pullman car conductor; that this man was admitted as a patient to the Hôtel Dieu, and not being carefully isolated, he communicated the disease to attendants and other patients, causing an epidemic in the hospital. The hospital was then closed, and the inmates leaving, distributed the disease through the city. The local health authorities are severely blamed by the Canada *Medical Record* for not having any provision for receiving and isolating small-pox patients.

The Western Pennsylvania Medical College is the name chosen for the newly organized college in Pittsburg, Pa. We are informed that it has been liberally endowed, and will begin lectures in October next.

Dr. Daniel G. Brinton, whose work in American Ethnology was recently very favorably criticised in the *Atlantic Monthly*, has been made laureate of the Société Américaine de France for 1885, and has been awarded the medal of the Society for his works on the aboriginal tongues of America.

The Blind in Russia number 1 in 125, while in most European countries the proportion is only 1 to 1,000 or 1,200. The ratio given for Russia, however, applies only to young male adults, and not for the whole population.

Recognition of Italian Women Physicians.—The first official recognition of female medical practitioners has just been made by the Italian government. The recipient of this distinction is Signorina Terne, M.D., whom Queen Marguerita has appointed one of her physicians in ordinary.

The Medical Department of the University of Tennessee held its Annual Commencement in Nashville, on February 26th, and graduated a class of 57 doctors and 13 dentists.

There is a Bill before the Virginia Legislature for a "Homœopathic State Board of Examiners," and as there are only fifteen homœopathic practitioners in the State, according to the *Virginia Medical Monthly*, it is proposed that the homœopaths appoint a committee to examine in materia medica and therapeutics such candidates as signify an intention to practise homœopathically.

Emetic Doses of Ipecac in Suffocative Cases.—Dr. L. Emmett Holt, of New York, writes: "In your report, in the last issue, of the discussion at the Academy of Medicine on 'Infantile Bronchitis,' I am reported to have said that at one time I was much averse to the use of ipecac, but on further trial thought it beneficial in selected cases. The point was not regarding the *use* of ipecac, but *emetic doses* of ipecac in the suffocative cases."

The Hospital Cottages for Children at Baldwinville, Mass., are about to be enlarged by a building to be devoted entirely to the care and treatment of epileptic children. It is to be completed by the middle of June, and will accommodate thirty-five patients.

M. Pasteur has been knighted with the "Grand Cross of the North Star" Order by His Majesty King Oscar of Sweden.

Emeritus Professor C. G. Santesson, of Stockholm, the famous anatomist and surgeon, died of paralysis of the heart in his sixty-fifth year.

Nominations for Health Officer and Quarantine Commissioners.—Governor Hill, of New York, has sent to the State Senate the following nominations: Dr. Charles H. Phelps, of New York, for Health Officer of the Port of New York, and Dr. J. Douglas, Marshal B. Blake, of New York, and Charles S. Higgins, of Brooklyn, as Quarantine Commissioners. The medical gentlemen named—Drs. Phelps and Douglas—will make good appointments, and will carry with them the respect and endorsement of their professional brethren in this city. Dr. Phelps is one of the representative surgeons of this city, and holds many positions of trust with great credit to himself. He has been for many years, and is still, surgeon to Bellevue and St. Vincent's Hospitals. Dr. J. H. Douglas is widely and favorably known as one of the physicians who attended General Grant, and will bring to his new office those sterling qualities of a skilled physician and upright gentleman for which he has been noted by his many friends. As we go to press the nominations have not been confirmed, although there are good reasons for beleiving that they will be.

Seven Deaths From Foot-ball have been recorded in the English journals during the past season. The last victim was a young man twenty-five years of age, who was kicked in the stomach.

German Doctors with Bogus Diplomas.—It is reported that proceedings are about to be instituted in Germany against a number of persons styling themselves "Doctor" on the strength of diplomas purchased *in absentiâ*. In Berlin alone there are said to be 3,400 of these "doctors," either of medicine, philosophy, or law. *The Lancet* states that all the bogus diplomas were purchased in America, but this is hardly fair.

Ligaturing the Subclavian with Catgut.—At the meeting of the Academia Médico-Quirúrgica Española, on January 12th, Señor Ustariz described a successful case of ligature of the subclavian artery with a catgut ligature, prepared with corrosive sublimate, for an axillary aneurism of the size of an orange. The patient left the hospital cured fifteen days after the operation.

The Nomenclature of Brain Diseases.—In pursuance of a resolution passed at the Medical Congress on Brain Diseases, held during the last summer at Antwerp, by which it was suggested that local conferences should be held to draw up trustworthy international tables of statistics on insanity, a conference of Austro-Hungarian specialists will be held at Vienna on the 26th and 27th inst., with the object of revising and extending the nomenclature of mental disorders. Invitations to the conference have been issued by four leading medical men of Vienna.

A Strike among Medical Students.—The medical students of the Brussels University have for some time refused to attend the lectures or continue their studies. Their return to the University does not seem probable at present. The reason they advance to explain their conduct is the dismissal of the clinical professors by the administration of the hospitals, in order to replace them by others of their own choosing. The Brussels University is quite independent of State protection.

Very True.—The distinguished President of the American Medical Association writes to the *Canada Medical and Surgical Journal*, with regard to the International Congress, that "when the medical savants of Europe come to Washington they will be much surprised at the scientific papers presented, and the discussion had upon their own papers." We quite agree with the eminent correspondent.

Nitrous Oxide as an Anæsthetic.—M. Laffont, in a recent communication to the Paris Société de Biologie, stated that nitrous oxide is a most dangerous anæsthetic. He has since further prosecuted his experiments, and at a subsequent meeting confirmed his previous statement. He has found proof that nitrous oxide is not an anæsthetic, but an asphyxiating agent, as MM. Jolyet and Blanche have proved. When this agent is used by dentists to produce anæsthesia, hyperglycæmia and glycosuria result. M. Laffont has verified these phenomena by personal experience. He has also ascertained that in animals these results take place before anæsthesia, during the period of deep breathing.

The Initial Stage both of Mumps and Measles is highly infectious, according to Dr. William Squire, in *The Lancet*.

The Medical Department of the University of the City of New York held its forty-fifth annual commencement on March 6th, and graduated a class of 173. The Hon. Wayne MacVeagh delivered the address to the class. The medallists were: Dr. S. Green (gold medal), Dr. T. D. Merrigan (silver), and Dr. M. L. Ford (bronze). Drs. E. J. Lorenze, W. T. Gibb, D. D. Jennings, and G. H. Coombs took hospital appointments; Drs. J. L. Babcock, D. H. Sprague, and B. F. Pierce took the faculty prizes. Dr. J. J. Quigley delivered the valedictory.

Chenopodium and Rupture of the Stomach.—A girl, aged twelve, living at Trenton, N. J., died suddenly of rupture of the stomach, as *post-mortem* showed. She had been taking a mixture containing chenopodium in considerable quantity, and the friends brought suit against the doctor in attendance, Dr. E. Rogers, claiming that the medicine caused the rupture. This, of course, was not sustained, and the jury returned a verdict exonerating the physician.

A New Society in Boston.—A therapeutical society has been organized in Boston, with Dr. A. F. Pattee, President; Dr. Albert Day, Vice-President; Dr. W. F. Mead, Treasurer; and Drs. A. H. Wilson and J. W. Johnson, Secretaries.

"The Nightingale" is the title of a new periodical, published in the interests of nursing, and edited by Dr. Sara E. Post. There seems to be an excellent field for such a paper, and its first issue is a creditable one.

The Medical Department of the Arkansas Industrial University held its Annual Commencement on March 5th. The valedictory was delivered by Professor T. E. Murrell.

The Health Officer's Fees.—Health Officer Smith has made a report to the State Senate with regard to the work of his office. It appears that in the past four years he has received $203,140, and disbursed for expenses $93,923, leaving a balance of $109,217, or about $27,000 per year.

Resolutions in Memory of the Late Dr. Alfred C. Post.—*Whereas*, It has pleased an All-wise Providence to remove from our midst Dr. Alfred C. Post, his former colleagues of the Medical Board of the New York State Woman's Hospital have unanimously

Resolved, That to the life and services of Dr. Post, and to their long and intimate association with him, they look back with grateful remembrance, while the memory of his many virtues and his constant devotion to duty adds to their sense of his loss.

Resolved, That during an exceptionally long and busy career, he never lost sight of the higher interests of the profession; and he discharged his duties, even in the smallest detail, to the various societies, hospitals, and institutions of learning with which he was connected, with rare fidelity. In his connection with the Woman's Hospital, as senior consulting surgeon and president of the medical board, he took an earnest interest in that insti-

tution, and was ever ready to aid his colleagues with his experience and his counsel.

Resolved, That these expressions of affectionate respect for Dr. Post's memory be printed in the medical journals of New York, and be respectfully transmitted to his family.

JAMES T. HUNTER, M.D.,
CHARLES CARROLL LEE, M.D.,
For the Medical Board.

March 8, 1886.

DR. MIDDLETON GOLDSMITH'S BEQUEST TO THE NEW YORK PATHOLOGICAL SOCIETY.—The following note, addressed to Dr. John C. Peters, will explain itself:

DEAR PETERS: I hereby agree to give in trust to the New York Pathological Society (when incorporated) ($2,000) two thousand dollars, in money or securities, as the Society may elect, and promise to give by will ($3,000) three thousand dollars more, payable at the death of my wife and myself. This promise, I am assured, is good in law. Yours very sincerely,

M. GOLDSMITH.

RUTLAND, VT., March 3, 1886.

Reviews and Notices.

DISEASES OF THE LUNGS (of a specific, not tuberculous, nature). By PROFESSOR GERMAIN SÉE, Physician to the Hôtel Dieu, Paris, etc. Translated by E. P. HURD, M.D. Pp. 398. New York: William Wood & Co. 1885.

THE subjects discussed under the above heading are Acute Bronchitis, Infectious Pneumonia, Gangrene, Syphilis, Cancer, and Hydatids of the Lungs. It goes without saying that the tone of the discussion of these topics is throughout dignified and convincing. Perhaps the most interest will centre about the chapters on Pneumonia. In order that a frank fibrinous pneumonia may develop, "it is necessary that a specific agent, a special microphyte, shall be brought in contact with the pulmonary tissue and there multiply. Ordinary frank fibrinous pneumonia, then, is an infectious disease, not in the sense of being a general disease, but in the sense of being a parasitic microbic disease." The author regards an etiological unity as existing between sporadic pneumonia and epidemic pneumonia. Pneumonia remains local as long as the parasite does not pass beyond the bounds of the pulmonary parenchyma; but when it diffuses itself, and pervades the general circulation and various viscera, either by the blood-channels or the lymphatics, it becomes an infectant disease.

Part III. treats of the general therapeutics of the broncho-pulmonary inflammations, and is a general *résumé* of the various methods presented by different epochs in the history of medicine.

In the chapter on Syphilis of the Lungs, three queries are made concerning those pulmonary lesions whose syphilitic nature is still under dispute: 1. Can syphilis determine, in the pulmonary tissue, lesions similar to cirrhosis of the lungs? 2. Is pulmonary cirrhosis frequently associated with visceral syphilis? 3. Do there exist special characters attributable to syphilitic pulmonary cirrhosis? To the first a full, and to the second a partial, affirmative answer is given. The third point is regarded as still under dispute.

The translator's preface is a concise statement of the present aspects of the germ theory of disease. He has been able to secure, as appendices to the volume, an article on Bacteria, by Dr. Dujardin-Beaumetz; also a reprint of Dr. George M. Sternberg's article on the Pneumococcus of Friedländer. The latter may or may not be regarded as having confirmed the main thesis of the author of the chapter on Pneumonia; they (Dr. Sternberg's studies) certainly have opened up a most interesting line of inquiry as to the possible morbiginous influence, under certain conditions of depressed vitality, of bacteria which are occasional components of healthy animal fluids.

A SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS. Edited by WILLIAM PEPPER, M.D., LL.D., assisted by LOUIS STARR, M.D. Vol. II.: General Diseases (continued), and Diseases of the Digestive System. Pp. 1312. Philadelphia: Lea Brothers & Co. 1885.

THE present volume concludes the general diseases, including rheumatism, gout, rachitis, scurvy, purpura, diabetes, urethritis, scrofula, and hereditary syphilis. Drs. R. Palmer Howard, William H. Draper, A. Jacobi, Philip S. Wales, I. Edmonton Atkinson, James Tyson, John S. Lynch, and G. William White are the gentlemen who treat of these topics. Dr. Howard's article on the various forms of rheumatism is very complete, and in descriptions of the various theories of pathology and of treatment he exhibits excellent judgment. Perhaps one might say here, as we said in commenting on the previous volume, that there is too much discussion and not enough of definite opinion. Yet it must be allowed that it requires considerable self-confidence to write dogmatically upon rheumatism. Dr. Howard appears to give in his adherence to a neuro-humoral view of rheumatism. He believes in the salicylates, and rightly inculcates their value in large doses in chronic rheumatism. He inclines to the neurotic view of the pathogeny of rheumatoid arthritis. It appears to us that he lays rather too little stress upon the value of electricity in rheumatic complaints. Dr. Draper's article on gout is a clear and scholarly presentation of this subject. He recommends a nitrogenous diet in the gouty dyscrasia. Dr. Jacobi's learned article on rachitis is concluded with an interesting description of the best methods of feeding infants. The author condemns infant foods entirely, and recommends the familiar oat-meal and barley-water diluents. Dr. Jacobi believes that small doses of phosphorus are useful in rickets. Dr. Tyson gives us, on the whole, a very good monograph on diabetes mellitus. This includes the description of a number of tests for sugar and several diet-tables that will be found useful. The description of the clinical history of diabetes is somewhat meagre, especially as it is well known that the disease has several somewhat distinct types. The loss of the tendon-reflexes and the peculiar relations of diabetes to tabes also do not receive notice. Dr. Welch's articles upon ulcer of the stomach, cancer of the stomach, hemorrhage from the stomach, dilatation of the stomach, and minor organic affections of the stomach, are among the best in the book, particularly from the pathological point of view. A large number of valuable statistics and other data have been collected, so that the articles have more of freshness and originality than is the case with many of the other contributions. Of the articles on diseases of the intestines, by Dr. W. W. Johnston, Dr. Lewis Smith, Dr. Wales, Dr. Whittaker, Dr. McGuire, and Dr. Atkinson, we have not space to speak. Dr. Alonzo Clark's article upon peritonitis will be read with interest. It is perhaps the best monograph that has come from Dr. Clark for a long time. Dr. Bartholow's articles upon diseases of the liver are written in a clear and attractive style, and together furnish a very complete account of the disturbances of this important viscus.

THE RATIONAL TREATMENT OF RUPTURE. A Study of the Causation, Pathology, and Varieties of Hernia. By DR. A. H. PARKER. Chicago: Shea, Smith & Co. 1885.

A BOOK describing a form of truss devised by the author for the relief of inguinal, femoral, or umbilical hernia.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 13, 1886.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

REPORT OF THE COMMITTEE ON MICROSCOPY.

DR. WALDSTEIN reported that the specimen presented by the President at a former stated meeting was a tubercular testis; also that the small tumors presented by the President, removed from the antitragus, were cartilaginous growths. In both instances the diagnosis was corroborated by the microscopical examination.

Dr. Waldstein also remarked that since the presentation of the latter specimen he had seen two children, one six and the other three or four years of age, in whom there were small cartilaginous growths before the antihelix, but not sufficiently large to be of special importance.

DR. A. G. GERSTER presented a specimen of

PERIOSTEAL SARCOMA OF THE THIGH,

removed by amputation from a girl, twenty-six years of age, who about three years ago fell down stairs, but was not aware, at that time, that she received any severe injury. From that date, however, she began to notice a slight disturbance of the function of the knee-joint, apparently due to the development of a swelling corresponding to the external condyle of the right thigh. The disturbance of function was not so much from pain as from mechanical difficulty in bending the knee, especially in ascending stairs. When she presented herself to Dr. Gerster he found a hard, non-movable tumor occupying the site of the external epicondyle. Puncture with the hypodermic needle was negative, and the tumor gave no parchment-like crackling sensation, but it was noticeable, at one portion in the popliteal space, that it was rather movable. Dr. Fluhrer and the other surgeons regarded it as possibly a group of infiltrated glands. The shaft of the femur corresponding to the internal epicondyle was perfectly intact, and the entire tumor was superimposed upon the cortex of the bone. If it had been a central sarcoma the tumor would have been spindle-shaped. Another interesting feature of the specimen was that the movable mass regarded as lymphatic glands had been demonstrated to be such as was diagnosticated. The new growth was confined strictly to the diaphysis.

Dr. Gerster assumed that it was malignant in character, but he invited Dr. Markoe, who had had a large experience in the observation of the class of tumors known as enchondromata, to see the patient with him, whose opinion, after a complete examination, was rather strongly in favor of the tumor being an enchondroma. He thought they might have to deal with one of those osseous growths with a pedicle and a mushroom-shaped top which could be easily chiselled away and the limb of the patient saved. The puncture, however, made it evident that the tumor had a soft centre, and the fact that there was in the inguinal region of the affected side a group of glands somewhat more enlarged than those on the opposite side, with the additional fact that the general condition of the patient had suffered severely, led Dr. Gerster to regard it as undoubtedly sarcomatous, and amputation was at once performed.

Dr. Gerster also presented a specimen of

MYXO-SARCOMA OF THE TESTICLE,

removed from a patient thirty-two years of age. The cause was obscure, as there was no history of traumatism or inflammatory process. The tumor was about the size of his fist.

UNDESCENDED TESTICLE—HERNIA—OPERATION—CURE.

Dr. Gerster also presented a specimen removed from a man, thirty years of age, who since childhood had noticed only one testicle in his scrotum. When he was about eighteen years of age a hernia appeared, and when an attempt was made to wear a truss the patient found that the pressure of the instrument caused excruciating pain, whereupon the truss was removed, and the hernia since that time had developed into large proportions. Gradually during the last four or five years a rather hard body had descended into the inguinal region and vicinity of the external abdominal ring, alongside the hernia, painful on touch, and if he kept on his feet attending to business the pain would become so severe as to compel him to stop work. Dr. Gerster found on examination that he had to deal with an undescended testicle, and also a hernia in which there was a considerable portion of omentum which could not be replaced completely. Consequently he concluded that the omentum had become attached to the hernial sac by inflammatory process. He advised the patient to submit to a radical operation on the hernia, which was performed in the Mount Sinai Hospital, and, when the sac was exposed, it was found that external to it there was situated a body composed of fatty tissue, resembling a lipoma, containing in most of its parts a rather small proportion of connective-tissue elements, except at the upper extremity, which was close to the inguinal canal, where a rather hard mass of tissue was found which appeared to him as possibly sarcomatous in character, but it was found to be composed principally of the remains of an inflammatory process.

The sac was opened, and it was found that it was occupied by a large portion of omentum which was adherent almost the entire length of the sac in the inguinal canal. It was dissected up without much trouble, deligated in several pieces, cut off, and the stump placed in the abdominal cavity. The sac was transfixed with catgut suture in a way which might be compared to the string of a purse; it was tied, and then cut off, and the stump was placed in the inguinal canal. The pillars of the external ring were brought together with stout catgut, leaving a little slit for the exit of the spermatic cord. The atrophied testicle was removed.

There was no elevation of temperature after the operation, and the entire wound healed by first intention. On the fourteenth day slight hemorrhage occurred when the patient attempted, contrary to orders, to lift a body of some weight. The hemorrhage was due apparently to the severing of the deeper portion of the newly formed cicatrix. A slight sinus remained which required slitting open, but which then healed readily, and the patient was dismissed cured, with the advice to wear a light truss.

Dr. Gerster believed that the radical cure of inguinal hernia was doubtful, but at the same time the operation does some good, as it enables the patient to wear a truss, perhaps in a way which will prevent the return of the hernia. The so-called radical cure by means of injections of astringent solutions, Dr. Gerster thought did not deserve the name of radical cure.

RETENTION-CYST OF THE SUBMAXILLARY GLAND.

Dr. Gerster also presented a mucous cyst, removed from the floor of the mouth of a man twenty-six years of age. It had been diagnosticated as a ranula, and an incision was made into it from the oral cavity by another surgeon. It was a large tumor when filled, and interfered seriously with deglutition and even respiration. The tongue protruded from the mouth, became dry, and the patient was unable to attend to his business on account of the unsightly appearance of his face. Incision and drainage practised by the former surgeon did not result in cure. The tumor collapsed but the drainage-tube could not be retained, and was removed, and the wound healed; but a short time afterward a reappearance of the tumor was noticed, whereupon he presented himself at Dr.

Gerster's clinic, when he found a fluctuating tumor from which he withdrew fluid which proved to be mucoid in character; a turbid liquid containing a rather large proportion of pus-cells. Extirpation was advised, and was performed in October in the Mount Sinai Hospital, and the tumor was found to be a retention-cyst of the submaxillary gland. The specimen showed the body of the gland, and the sac of the cyst formed a continuation of the glandular capsule. One peculiar fact concerning the tumor was that it grew toward the median line, thus producing the impression that they might have to deal with a dermoid cyst. The dissection for its removal extended downward to the hyoid bone. The oral cavity was not invaded, as it was possible to exsect the sac of the tumor from the old cicatrix left by the preceding operation of tapping and drainage. This rendered the case much simpler than it otherwise would have been. The submaxillary, the facial and the lingual arteries were deligated before removal of the cyst.

THE PRESIDENT said, concerning radical cure of hernia, that Dr. Gerster's experience was the same as his own, with regard to the result of these operations. He had operated about twenty times. He knew he had cured one patient, and there was another in whom he had suspected a cure had been effected by Heaton's operation, performed on a boy ten years of age. It must be admitted, however, that a cure can frequently be effected in a patient of this age by wearing a truss, which exerts a sufficient degree of pressure. He always advised patients to wear a truss after any operation for radical cure has been performed.

DR. CHAS. H. KNIGHT presented a specimen of

FIBROMA OF THE VOCAL CORD, REMOVED WITH MACKENZIE'S FORCEPS,

accompanied with the following history:

J. M——, aged fifty-seven, iron moulder, family history good. Patient has always been well. Two years ago first noticed trouble in speaking; voice became husky and occasionally "cracked;" unable to sing as formerly. Dry cough. No history of any treatment.

With the laryngoscope a neoplasm the size of a French pea was seen at the junction of the anterior and middle thirds of the right vocal cord, perfectly round and smooth, of a livid red color, in striking contrast with the white vocal cord to which it was attached. It had a very short pedicle and during phonation it rested between the cords, being attached just at the margin of the right. There was a moderate degree of laryngitis, the left cord was almost normal, the right being especially congested, not in the vicinity of the growth, but at its posterior extremity.

The larynx was very capacious and tolerant. After thorough spraying of the fauces and larynx with a four per cent. solution of cocaine hydrochlorate, two unsuccessful attempts were made to remove the growth with Mackenzie's laryngeal forceps. One week later the growth was removed with the forceps on the second trial. There was very little hemorrhage. Six days after the operation the vocal cord was found to be perfectly smooth and normal, with the exception of slight congestion. The voice was almost natural and the patient said he had even been able to sing. It has since been learned that the patient had been under treatment for nearly three months, and that several attempts had been made to remove the tumor with chromic acid, with forceps, and with the sponge probang by the method of Voltolin's. The specimen was referred to the Committee on Microscopy.

DR. T. MITCHELL PRUDDEN presented a specimen which illustrated

CONGENITAL ABSENCE OF THE LEFT KIDNEY.

The specimen was removed from the body of a man twenty-two years of age, who had given no symptoms of renal disease, and who died of *phthisis pulmonalis* and *tubercular meningitis*.

On the left side the supra-renal gland was in about its normal position and was somewhat broader than usual. The left kidney and ureter were absent, there being not even a rudimentary trace of those parts. There was no left renal artery.

The right kidney was moderately enlarged, measuring twelve centimetres in length, and was a little thicker than normal. The right ureter was slightly wider than normal.

There were no other malformations in the body.

Microscopically the right kidney is normal in structure. The cortex tubules and glomeruli are plump and large, but without careful measurements it would not be possible to say that they are actually hypertrophied.

The case seemed to him worthy of presentation and record, not only because it was an excellent example of this form of malformation, but because, owing to the greater frequency of the operation of removal of the kidney in late years, a more exact statistical knowledge of the frequency of this malformation was for obvious reasons desirable. Up to 1883, according to Guttmann, there were within twenty-five years about seventy cases on record in which one kidney was entirely absent or represented by a mere rudiment.

DR. WESLEY M. CARPENTER remarked that two or three years ago he saw in the post-mortem room at Bellevue Hospital at least three cases in one winter with only a single kidney present. If memory served him correctly, one of those was an operation case, in which the only kidney the patient had was removed. One specimen, brought to the Wood Museum, was removed by Dr. Welch from the body of a late distinguished surgeon of this city. He also had in his collection a single kidney which, at the time of removal, weighed twenty-four ounces, and which was the seat of simple parenchymatous nephritis. He had not seen cases of single kidney prior to nor since that date, covering a period of twelve years; thus showing that their frequency was not very great.

THE PRESIDENT remarked that he once directed considerable of his attention toward the viscera of the abdomen with reference to abnormalities affecting the arteries, and of the many bodies which he examined for this purpose, he had no recollection of encountering one in which there was only a single kidney.

DR. W. P. NORTHRUP said that out of a thousand autopsies made on babies he had not encountered one in which there was only one kidney.

DR. GERSTER said that, among the first operations which he performed in this country, was one on a child with imperforate anus. During the operation he encountered a hard body which resembled in appearance a portion of intestine, and it was incised and urine came from the bottom of the wound. The child died, and it was found that it had but one kidney. The explanation of the case was found in the fact that one ureter was distended so much that it resembled a small intestine in size and in thickness of its walls, having been occluded where it should have entered the bladder.

ACUTE MILIARY TUBERCULOSIS.

DR. L. EMMETT HOLT presented the lungs, liver, kidneys, and spleen of a male child four months of age, which died at the New York Infant Asylum on January 8th.

The parents and other child were healthy, and no history of tuberculosis could be traced in the family. The child was the smaller of a pair of twins, and had always been plump and well nourished, being nursed at the breast.

The child had symptoms of an ordinary mild bronchitis for a week or ten days prior to January 4th, when its first marked rise of temperature occurred, it reaching 102°. Up to this time it had not been above 99°. With the fever all the symptoms were much aggravated. The respirations were 64 and the pulse 180. There were

now the signs over the whole chest, the signs of bronchitis affecting the larger and medium-sized tubes.

The temperature rose the next night to 103°, and on the two succeeding nights to 105 and 104 respectively. On the morning of January 7th, the child was much better in its general symptoms. The temperature had fallen to 100°, the respirations to 60, and the pulse to 160. A small spot of bronchial respiration was found at each extreme apex behind, but no dulness and no signs elsewere in the lungs of consolidation. The râles were less numerous. The case was regarded as one of severe bronchitis, going on to broncho-pneumonia. Very unexpectedly it grew worse, and died the next morning, January 8th, after four days of febrile symptoms.

The autopsy was made thirty-two hours after death. Body plump and well nourished. Brain carefully examined, but no tubercles found anywhere, and no signs of disease. Thorax: There were no pleuritic adhesions. Both lungs showed widespread tubercular changes. At the extreme apex, and along the posterior borders of both sides there was a narrow strip of consolidation which widened out in the lower lobes to involve perhaps one-third the lobes. On section these consolidated portions were found studded with miliary tubercles. The rest of the lungs were pretty thickly sprinkled with tubercles, the surrounding lung tissue being, for the most part, healthy in appearance. There was no lymph on the pleura anywhere. The bronchial glands were enlarged to the size of an ordinary bean, but not cheesy on section. No tubercles were seen in the pericardium. The liver showed a small number of tubercles scattered over its surface, and was slightly fatty. The spleen weighed one ounce and a half more than double the ordinary size. It was studded with miliary tubercles, and had many round cheesy masses on its surface from one to two lines in diameter. The kidneys presented nothing abnormal except a very few tubercles on their surface. Mesenteric glands slightly enlarged, not cheesy. No tubercles seen in the peritoneum.

The case was an illustration of what is not at all infrequently seen, that a child, previously healthy, may die unexpectedly from tuberculosis, where neither the symptoms nor physical signs, during life, have given the slighest reason to suspect its existence.

Dr. W. P. Northrup presented a specimen with the following history:

DIPHTHERIA—CROUP—O'DWYER'S TUBE—DOUBLE PNEUMONIA—DEATH.

The patient was an inmate of the New York Foundling Asylum, aged three and one-third years, female.

Previous to present illness her condition was good, no previous disease. The history is as follows:

December 24th.—Croupy cough. 8 P.M.: Pulse, 138; respiration, 20, temperature, 103° F.; moderate obstruction in respiration. 10.30 P.M.: Marked obstruction, very restless, coughed up membrane. Dr. O'Dwyer inserted his croup tube. (Tube here shown to the Society.) Ten minutes later patient sleeping quietly. All obstructions gone, tube causing less irritation than usual.

December 25th.—Condition good. No dyspnœa. Takes food well. A.M.: Pulse, 168; respiration, 28; temperature, 103° F. P.M.: Pulse, 180; respiration, 36; temperature, $104\frac{8}{10}$° F. Coughed up membrane.

December 26th, 1.30 A.M., twenty-seven hours after insertion, tube removed. 3 A.M.: Marked obstruction again, croupy cough and respiration. 8 A.M.: Pulse, 178; respiration, 42; temperature, $104\frac{6}{10}$° F.; albuminuria, thirty-three and a third per cent., by bulk.; no casts. 6 P.M.: Severe paroxysm of dyspnœa. 6.35 P.M.: Marked obstruction, cyanosis, restlessness.; tube inserted by Dr. Dillon Brown, the house physician—prompt relief. 7 P.M.: Pulse, 168; respiration, 44; temperature, $103\frac{2}{10}$° F.; quiet, color good, bright, bronchial râles both sides.

December 27th.—Slept well. Condition best for three days. Cheeks flushed, nostrils dilating. 6.30 P.M.: Pulse, 168; respiration, 48; temperature, $104\frac{6}{10}$° F.; asleep for first time to-day; pus and fibrin exudate on both tonsils for the first time. 9.45 P.M.: Tube removed, obstruction marked. Tube was removed to see if possibly there might be some laryngeal obstruction—tube quite clear. 10.15 P.M.: Tube reinserted. Patient continued to fail rapidly with symptoms of pneumonia, and died quietly at 10.30 P.M.

Autopsy, December 28, 1885. Body well nourished. Pharynx: Pseudo-membrane on tonsils and posterior wall. Larynx, trachea, bronchi, to the finest possible to trace, show a thick tenacious, continuous, hollow cast of pus and fibrin exudate. This is the most tenacious and extensive ever seen at asylum dead-house table. Lungs: Extensive pneumonia of both; color mahogany, punctate hemorrhages into visceral pleura. Bronchial glands enlarged and dusky, firm. Heart normal; muscle teased fresh, no degeneration of its fibres. Liver and spleen normal. Kidneys: Moderate parenchymatous change. Stomach and intestines normal.

In presenting the tube developed by Dr. O'Dwyer, it was not the purpose here to give his complete records, but to speak casually of his last twelve cases at the New York Foundling Asylum. In all there was albuminuria; in all the tube was put in and relieved promptly the laryngeal obstruction. In all it was withheld till the signs of urgent dyspnœa were present, viz., cyanosis, restlessness, marked recessions on inspiration. This was to place it on a footing with tracheotomy, a later resort. Three of the twelve have recovered. One other lived to the sixteenth day, and on autopsy, tuberculosis with recent pneumonia was found.

Certain questions will certainly arise, and the answers in anticipation may be summarized as follows: The tube has never failed to relieve laryngeal dyspnœa. There is no ether, no wound, no shock. To insert the tube requires but a few seconds. The tube cleans itself. It is so made as to be coughed out if, by chance, any membrane plugs it from below. This has occurred. In a case of Dr. Northrup's in private practice, the tube was removed by Dr. O'Dwyer after fifty-eight hours, and found entirely clear.

The insertion of this tube requires some manual dexterity. Every practitioner will agree to pass a catheter into the larynx, but this is less difficult. It does, however, require practice. In conclusion: "To those who remember their first experience in taking care of a tracheotomy case after the operation, the continuous watching at the bedside, their constant manipulations with feather and solvents and inner tube, their continual anxiety, I may say that in this simple device the patient is relieved, and the doctor's life is not quite miserable."

The following is a cursory survey of sixty-one recorded cases of children dead of laryngeal diphtheria or membranous croup, showing extent of pseudo-membrane:

Extending from pharynx to finest bronchi, 22; pharynx to bifurcation of trachea, 9; larynx to first division bronchi, 21; larynx to second division bronchi, 4; larynx to fourth division bronchi, 3; pharynx and trachea, 2; croup first symptom, 49; membrane in pharynx first, 12; pneumonia occurred in 44.

Dr. C. H. Knight asked if the tube had been known to produce erosion of the vocal cord.

Dr. Northrup said the rule at the Asylum had been to remove the tube at the end of twenty-four hours, and allow the child to cough and clear out the trachea, and then put the tube back. In one case in which it was allowed to remain in position nearly all the time for four days there was a slight superficial rubbing off of the epithelium, but he had never seen any ill effects produced on the vocal cords as the result of the wearing of the tube; the slight erosion occurred at the end of the tube.

Dr. Holt asked how long the tube had been allowed to remain.

Dr. Northrup replied that in one case it was permitted to remain about one week, and without any detriment whatever.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 4, 1886.

Abraham Jacobi, M.D., President, in the Chair.

The Corresponding Secretary announced the death of

ASHBEL SMITH, M.D.,

of Texas, a Corresponding Fellow of the Academy, which occurred on January 21st, of pneumonia, in the eightieth year of his age. He held prominent positions under President Houston, when Texas was a republic, and was the most eminent medical man in the State.

Dr. D. B. St. John Roosa read a paper entitled

LIMITATIONS IN THE VALUE OF GLASSES FOR THE IMPROVEMENT OF VISION AND THE RELIEF OF DISEASE,

in which he first referred to the system of test-letters presented to the medical profession in 1854, in England, by Alfred Smee, and in Germany by Edouard Jaeger.

This was the first attempt to arrange an accurate method of estimating visual power. But these were very insufficient, and afterward came Snellen's test-types, which virtually solved the problem of making a register of visual power.

With Jaeger's test-types, which are still used as the standard test of capacity to read, and Snellen's letters for the determination of vision at twenty feet, about as accurate an account as is necessary of a given person's vision can now be given.

The ophthalmoscope was invented in 1851; yet, as late as 1854, little more than mention was made of the instrument in text-books, as well as of the necessity of the correction by test-glasses of the numerous anomalies of refraction and accommodation. Indeed, all this sprang from Helmholtz's discovery. Without the ophthalmoscope the determination of the refraction with accuracy was impossible.

Donders' great work was made accessible to the English-speaking people, by Dr. Moore's famous translation, in 1864. Through all these stages has come the ophthalmic science of to-day, and now a large part of the time of specialists is spent in adjusting glasses for impaired or weak vision. Beyond this, glasses are worn when there is no evident impairment of sight. Patients suffering from headache or from vertigo are now very often sent to the oculist to determine whether these symptoms may not depend upon a lesion of refraction or accommodation.

But it must be stated that defects of sight are often only one, and sometimes only a temporarily acting, factor in the production of neuroses.

Too much stress should not be laid upon the curative power of the correction of the error of refraction, as we shall often meet with cases that we can with difficulty reconcile with theories of their sole influence, or that of a want of equilibrium of the ocular muscles.

Blepharitis ciliaris, styes, epiphora, have also come to be considered by many authors as intimately associated with, if not caused by, optical conditions of the eye, and one writer, at least, goes a step beyond anything as yet indicated, and considers the eye as a prolific source of reflex irritation. This writer inquires "if an irritation originating in an injured or degenerated eye may also give rise to disturbances in distant organs—for instance, the heart, the kidneys, or the muscles of the extremities"—and he answers this inquiry in the affirmative and cites illustrative cases which are thought to prove this. Neuralgia, chorea, insomnia, and epilepsy are diseases which the writer just quoted enumerates as those which may be caused by "difficulties in performing the function of sight."

All this is far beyond what Donders claimed for spherical or cylindric glasses when he issued his book. Donders recommended glasses for hypermetropia, astigmatism, and asthenopia, as well as for myopia and presbyopia, and Graefe made great use of prisms for the correction of muscular asthenopia dependent upon insufficient power of the internal recti; but neither of these men appears to have dreamed of glasses as a cure for headaches, epiphora, epilepsy, chorea, or uterine disease—for all of which they are now, in some instances, advised.

It is hard to overestimate the value of Donders' work in tracing the frequent source of asthenopia to hypermetropia. He stopped such practice as division of the external recti to relieve what was supposed to be spasmodic contraction of these muscles. His investigations have permitted thousands of young people to become educated men and women—young people who, before the days of convex glasses for hypermetropia, were condemned to sheep grazing and cattle ranches, without the benefit of light reading.

With a full appreciation, then, of the value of glasses in the improvement of vision, and even in the relief of disease, Dr. Roosa proceeded to speak of some of the limitations in their value, which prevented him from believing that the whole domain of reflex disease comes naturally under the care of the oculist, or that even all cases of apparently pure and simple asthenopia may be cured by glasses. He gave a series of fifteen cases, taken from his note-book almost without selection, which illustrated his subject, and which he hoped had been made clear enough to convey to the minds of his hearers the working theories under which he had been led to prescribe glasses. He could not accept all that was claimed by some authorities on the one hand, while, on the other, he feared that even after these years since the publication of Donders' work, the whole profession was not fully alive to the value, especially in cases with symptoms referred to the head and eyes, of properly adjusted glasses.

Uterine asthenopia, or the asthenopia so often found in women suffering from serious uterine disease, he had never been able to materially alleviate. Neither had he seen any benefit, other than very temporary, in the correction of trifling errors of refraction in neurotic hysterical subjects; nor from the weakness of ocular muscles, so often one of the early symptoms of locomotor ataxia.

That glasses will cure organic disease, or that the want of them will allow it to occur in parts remote from the head, he was not yet prepared to believe, and yet errors of refraction and accommodation are sometimes the cause of serious functional disturbances beyond those of vision; still, hypermetropes may live to become presbyopes without asthenopia Only when the failure of accommodation occurs from senile decay will they become aware, by the need of very strong convex glasses for close work, and the failure of distinct vision also, that they started in life with eyeballs of less focal power than many of their fellows. Some myopes go through life without ocular symptoms, while a long eyeball in others becomes a prolific source of evil.

While the correction of errors of refraction and accommodation, and the unburdening of overloaded ocular muscles, will do much to alleviate the asperities of human existence, these things are not as yet a panacea even for neuroses, much less for inflammatory diseases. In our hopes for cure in employing these methods, we still require to avoid scepticism on the one hand and excessive confidence on the other. *Medio tutissimus ibis.*

Dr. David Webster accepted all of Dr. Roosa's statements, and regarded his contribution as one containing a most excellent picture of the every-day work of ophthalmologists. Nearly all persons have some error of refraction; probably not more than half a dozen in one hundred have perfectly normal eyes. Why, under the same ocular conditions, some persons need glasses and others do not, probably depends, in most cases, upon the general condition of the person. He believed, with Dr.

Roosa, that there is a limitation to the value of spectacles, and that such affections as cataract, glaucoma, opacity of the cornea, diseases of the lids, etc., cannot be cured by glasses, as had been claimed by some doctors; that is, according to the statements made by the patients.

With regard to reflex neuroses, he had seen many patients cured by division of ocular muscles and the proper adjustment of glasses, and others relieved by the use of atropia and glasses.

Dr. Webster recalled cases of functional nervous disturbance in which the patients had been relieved by the use of prisms. In one case the patient suffered almost constantly from headache and other nervous symptoms, and he found insufficiency of the *externi* for distance, with a slight degree of hypermetropia, $\frac{1}{12}$. He ordered + 72 spherical, with a prism of 1° base toward the temple, over each eye, and to his surprise and gratification, the patient was relieved at once, and had worn glasses ever since. He had also used the Faradic current, as an adjunct, with benefit.

Dr. C. S. Bull said that his views coincided with those set forth by Dr. Roosa.

Dr. Gruening had frequently prescribed ordinary plain window-glass for the good eye, and ground for the deflected eye, in cases of dizziness and perhaps diplopia, and with benefit. Many such cases were ataxic, and the neurologists did nothing for the double vision.

Dr. W. O. Moore referred to a case of epilepsy which illustrated the limitation in the use of glasses.

Dr. R. W. Amidon agreed with Dr. Roosa concerning the universal application of glasses for neuroses, and thought that, perhaps, he would limit their use even more strictly. The use of window-glass for diplopia, under the circumstances mentioned by Dr. Gruening, had long been practised by neurologists.

With reference to headache, he had found that the frontal was very likely to be associated with errors of refraction, while the occipital came more frequently from insufficiency of ocular muscles.

He had seen wonderful results follow constant and temporary use of prisms, especially in cases of insufficiency of the interne muscles.

Dr. Roosa said that he had been pleased to hear that those who had participated in the discussion, both oculists and neurologists, entertained substantially the same doctrine which he had advocated, and especially so because they had been accused of falling behind the age in their appreciation of what can be done with glasses for the relief of human ills. He was unwilling to admit that there was any new pathological fact, or therapeutic agent, permanently successful, which was unknown to men working in the regular way in these two departments of medicine.

Dr. H. G. Piffard then exhibited

A NEW ELECTRIC LIGHT,

which was manufactured by the Galvano-Faradic Company, and was portable, fairly constant, and could be obtained at a moderate expense.

The Academy then adjourned.

Ambulance and Hospital Huts (Döcker's System), Copenhagen.—As may be known to our readers, a prize of 5,000 francs was offered by the Empress of Germany, at the International Competition of the Red Cross in Antwerp this year, for the best constructed ambulance hut. The special committee finally awarded the prize to the Danish Portable Döcker Huts made in Copenhagen. These huts are built of wood, so prepared as to be both water and fire proof; they are easily taken down and put up, being at the same time strong, and are portable; and can be easily cleaned and disinfected when necessary. The air space allowed per bed is from 12,836 to 14,170 cubic metres. They can be used singly, or several placed together, so as to form a larger building.

Correspondence.

OUR LONDON LETTER.

(From our [illegible] Correspondent.)

ENTERIC FEVER AT SUAKIM—DISCUSSION AT THE MEDICAL AND CHIRURGICAL SOCIETY—THE SURGICAL TREATMENT OF ACUTE NECROSIS—HUNTER'S HOUSE AT EARL'S COURT AND WINDMILL STREET—A NEW VIEW OF INFLAMMATION—A PRIVATE MEDICAL SCHOOL—THE COLLEGE OF SURGEONS.

[illegible]

The last meeting of the Medical and Chirurgical Society was entirely occupied in discussing the subject of enteric fever, the so-called typho-malarial fever, and their mutual relations. The discussion was based upon a paper read by Dr. J. E. Squire, and having for its title "Enteric Fever at Suakim, with some Cases of Malarial Enteric or Typho-malarial Fever." The author, a young London physician, had charge of a division of the Base Hospital at Suakim, and had observed eighty cases of fever. Seventy were of the ordinary enteric fever type, this being verified by necropsies on two cases. Of the remainder, some were so modified by climatic causes as to deserve the name of malarial enteric. Two or three showed stronger evidence of malaria. In one of these, which was believed to be enteric during life, no enteric lesions were found post-mortem. Dr. Squire thought that the term typho-malaria might be restricted to such cases. In two of the fatal cases subconjunctival or subcutaneous hemorrhages occurred. These were not due to scurvy, as the troops had fresh meat and vegetables. There was no typhus. Diarrhœa was a marked symptom in all cases of fever. As regarded the causation of the enteric fever, he thought the disease was imported from Cairo and spread by aërial infection. The exclusive use of condensed water for drinking and cooking purposes excluded water as a source of infection. The author concluded by pointing out that, contrary to the theories of some Indian and army medical authorities, the seasoned troops were attacked earlier than those unused to tropical climates, and the mortality was not higher among the younger soldiers.

Several medical officers belonging to the services were present and joined in the discussion. Surgeon-Major Meyers was inclined to think dysentery was at the bottom of a good deal of the fever at Suakim. Surgeon-General Marston maintained that recent arrival in a tropical country increased the susceptibility to enteric fever. He did not think there was any evidence of typho-malarial fever being a distinct disease, though, of course, a malarious subject might be attacked with typhoid fever and exhibit symptoms of both diseases.

Dr. Drewitt suggested that we had to do with a chemical union of typhoid and malaria and referred to some narratives in Dr. Whipham's "History of the American Rebellion." Dr. S. Thomson believed that the form of enteric was determined by the nature of the soil. He distinguished two types of typhoid: (1) abdominal, when water was the source of the poison; (2) diphtheritic, when the disease arose from inhaling sewer-gas. In the latter case the throat was more affected, and nervous symptoms were prominent. Brigade-Surgeon Don reiterated the military view, that enteric fever can originate *de novo*. Brigade-Surgeon Gribbon had no doubt that the cases at Suakim were enteric. Suakim, he said, was not a malarious place. Dr. Broadbent then spoke at some length. He said that the fact of the occurrence of enteric fever at certain ages and on recent arrival in a country, taught nothing as to the specific nature, or otherwise, of the disease. He was convinced that there was some other fever met with in tropical and sub-tropical climates, distinct from, though simulating to a certain extent, the course of typhoid fever. The second tropical fever could hardly be enteric fever modified by climatic and other con-

ditions. Experience had shown that we required some distinct name to express this second affection, and, perhaps, "typho-malarial" was the best term for a fever which was even more protean than enteric fever in its clinical course.

A brief but animated discussion followed the reading of a paper, at the last meeting of the Medical Society of London, by Mr. Bernard Pitts, Assistant Surgeon to St. Thomas' Hospital, on "Subperiosteal Section in Cases of Acute Necrosis." Notes of two cases were read. In the first, the patient, a girl of fifteen, was admitted with pain and swelling in the lower end of the right tibia. The patient was very prostrate and had a temperature of 102°. An incision had been made above the ankle, giving exit to a large quantity of matter. This was freely enlarged, and the patient's condition at once began to amend. But the improvement did not continue, and a month after admission a further operation was undertaken, and the lower two-thirds of the tibia removed, when it was found extensively necrosed. The epiphysis was almost entirely destroyed. Care was taken to save the periosteum. The astragalus was scraped and the epiphyseal remains removed. Some months later a small residual sequestrum was removed and a sinus in the foot was opened. The patient finally did well, and possessed in the leg a very useful limb, with but slight shortening. In the second case, a boy aged seven, the site of the disease was the same. An incision over the internal malleolus allowed the escape of some exudation. Later on, separation at the epiphysis was detected and two and a half inches of the tibia were excised. The bone was quickly regenerated and the patient was up and about in two months. When seen some months later, the limb presented but little deformity or shortening. Mr. Pitts said he divided cases of acute necrosis into five classes, as follows: (1) Acute necrosis of the entire shaft, with separation at the epiphyses; (2) where one or both joints are implicated also; (3) limited necrosis; (4) acute necrosis of either end of a long bone; and (5) acute necrosis with total destruction of the epiphysis and involvement of the joint. As to the treatment which, in his opinion, was advisable in these several cases, he said that in (1) the dead shaft should be removed. In (2) early interference is more imperatively demanded, but in some cases amputation is needed. In (3) we might usually give time for complete separation of the sequestrum. The second case he had described was an example of the treatment to be adopted for (4), and the first case an illustration of (5) and its treatment.

Mr. Clutton said Mr. Pitts' first case proved that the surgeon need not hesitate to remove living bone with the dead, for a good result could still be obtained. Mr. J. H. Morgan and Mr. Walter Pye narrated similar cases. Mr. Pearce Gould rather opposed the too early removal of sequestra, for much new bone might be removed. The final result of many cases showed that the sequestrum was frequently very small, compared with what we might have expected.

Another interesting historical memento is about to disappear. I refer to John Hunter's residence at Earl's Court. The house and grounds have been acquired for building purposes, and Hunter's former residence is to be pulled down forthwith to make way for some dozen modern flimsily built stucco villas. The old materials are to be sold by auction in a few days, and by the time these lines appear in your columns the British workman will have done his best to obliterate the traces of Hunter's presence. Earl's Court is now really a part of London, being within an easy walk of the museums at South Kensington, but at the time the great anatomist lived there it was different. The neighborhood was then unbuilt on, and Hunter's mansion, with its extensive grounds, stood adjoining the fields and within easy reach of the open country. Here it was that Hunter kept his famous menagerie of wild beasts. Curiously enough, Hunter's town residence is also at present under sentence of demolition, having been acquired by the Metropolitan Board of Works in connection with the street improvements now being carried out by them at the West End. This stands in Great Windmill Street, just at the top of the Haymarket, in a position which no modern surgeon would select as his residence. The street, however, is one of many which have fallen in status during the last fifty years. The house is a very good one, being a large double-fronted building of good elevation. Here it was that Hunter lived and practised for years. His private medical school was at the rear of the house, being, however, also approached separately through a narrow paved walk alongside the house, with a gateway in the street. The private house has been for years a French restaurant, in which I have ere now eaten a humble lunch. The medical-school premises have also undergone conversion, having been used as printing premises for twenty years or more. One of our weekly medical journals has been printed there for years. The top floor, a spacious room well lighted by skylights, which was Hunter's dissecting-room, has been used by the printers as the composing-room. I have been over the premises, and it is with a pang of regret I hear of their approaching destruction.

We are often reminded that, even in the most familiar fields of research, the ground is by no means exhausted, but that much rich material still remains to reward the diligent observer who knows how to look for it—and that, too, in apparently the most unpromising situations. Mr. Treves' Hunterian Lectures for 1885 were an illustration of this, and showed that, even on such hackneyed ground as the naked eye, anatomy of the intestinal canal and peritoneum, there remained valuable facts still to be gathered up even in this nineteenth century. Mr. Sutton's recent lectures at the College of Surgeons exemplify the same thing in the sister field of pathology. Inflammation is a subject which scarcely lays itself open to the suspicion of affording anything very striking or novel, but in his second "Erasmus Wilson" lecture, Mr. Bland Sutton brought forward a number of facts, observed by himself and other workers, which enable us to view the subject from an entirely fresh aspect.

Mr. Sutton defined inflammation as "the method by which an organism attempts to render inert noxious elements introduced from without or arising within it." In vertebrata the most important feature in the inflammatory process was the vascular disturbance. What originated this? If we extended our observations to the invertebrata we became quickly impressed with the important functions played by active motile cells. There were three points to which it was necessary to draw attention: (1) The capacity of certain cells to effect a change of place and form. This was an acknowledged fact in biology. Wharton Jones showed in 1846 that the leucocytes of human blood possessed this property. (2) Their power of taking into their interior various substances with which they may come into contact (pigment granules, etc.). (3) The property they possessed of decomposing organic material which had been taken into their interior, or was in contact with their protoplasm. This was termed intra-cellular digestion. Mr. Sutton described in detail numerous observations on this subject by himself and others. Metschnikoff, he said, had shown unquestionably that the wandering cells can digest organic substances. If fluids containing bacteria were injected beneath the skin of bipinuaria and others, or if they developed spontaneously in the wounds of such animals, they would soon be found within the substance of many amœboid cells. In many cases the bacteria lost their motility and became so delicate as scarcely to be visible. In vertebrates, in bacterial affections such as anthrax, the bacilli were taken up by the leucocytes.

Mr. Sutton then referred to a curious phenomenon presented by amœboid cells, viz., that two or more cells fused together to form a larger mass of protoplasm. Such masses were termed plasmodia. Metschnikoff had

watched their formation, and regarded them as equivalent to giant cells. In all cases in invertebrates they had arisen around foreign bodies, and always by fusion of separate cells. There was good reason to believe that giant cells in the higher vertebrata, when they occurred, arose from the fusion of leucocytes. Mr. Sutton referred to the observations of Metschnikoff on the absorption of the tails of larval batrachians. In the early stages numbers of amœboid cells were present within which were seen remnants of nerve and muscle fibres. These cells were in reality leucocytes engaged in devouring the tail of the tadpole, and had thus been named "phagocytes." The same observer had witnessed combats in the daphnia between the white blood-cells and bacteria, and, when one cell was not sufficient to attack the invading bacterium, two or more would fuse together, surround, digest, and thus rid the daphnia of the intruder. Could these facts be applied to mammals? If a rabbit's cornea were irritated, the tissue became red and hazy in a few hours, due to escape of leucocytes from the vessels to repel, or, if possible, to destroy the offending material. Draw a fine thread across the interior of a vein, and leucocytes soon swarmed around it. In tubercle, leprosy, perlsucht, or avian tuberculosis, the characteristic lesions swarmed with bacilli. These were often taken up by cells, and especially by giant cells. These facts seemed to show that in the giant cells we had the counterpart of the fusion of phagocytes, etc., and that it was in reality an effort of the blood-corpuscles to rid the blood of noxious elements. The "osteoclasts" seen in bone undergoing absorption must be placed in the same category.

These observations showed that the process of inflammation was one of normal physiology, but when in excess it came within the domain of pathology. Summarizing the story of inflammation as we read it zoölogically, it should be likened to a battle. The leucocytes were the defending army, the blood-vessels were the roads and lines of communication. In the conflict cells died and were eaten up by their companions. Frequently the slaughter was so great that the tissues were burdened by their dead bodies in the form of pus. These dead cells, like the corpses of soldiers who fell in battle, later became hurtful to the organism they had in life been anxious to protect from harm, for they served as breeding-grounds wherein the bacteria might germinate, and, like a pestilence and scourge, devastate the individual.

A serious accident has befallen Mr. Thomas Cooke at his private school of anatomy. A destructive fire has occurred and utterly destroyed a large number of valuable anatomical preparations representing many years of patient toil. Mr. Cooke's school of anatomy is a modern representative of what was common enough in former days, viz., a private medical school. It is the only representative of such an institution that we have in London, though "Minto House" is a somewhat similar one in Edinburgh.

Since facilities for dissection have been afforded by the passing of the Anatomy Act, dissection has been almost exclusively confined to the dissecting-rooms of the recognized medical schools. Mr. Cooke established his present school—which, by the way, is fully licensed—about fourteen years ago, and has continued to teach practical anatomy, physiology, operative surgery (on the dead body), and other branches of medical science ever since, with popularity and success. His course on operative surgery has received official recognition from the University of London. Many students and practitioners who owe some measure of their success in their examinational career to a course at "Cooke's" will regret to hear of the misfortune which has overtaken their former teacher.

The controversy at the College of Surgeons still, like a wounded snake, drags its weary length along. The members are about to petition the Queen in Council, and the Fellows are "down upon" Mr. Hutchinson on account of his motion to widen the basis on which the Fellowship can be obtained. This proposition appears to please nobody. The Fellows object to the cheapening of their diploma, and the members regard it as a sop at which only a few of them can get a bite.

SKUNK-BITE AND HYDROPHOBIA.

[illegible]

SIR: I notice in a recent issue of THE MEDICAL RECORD a communication concerning skunk-bite and hydrophobia. An experience covering several years, while connected with the United States Army in Kansas, Colorado, New Mexico, the Texan Panhandle, and the Indian Territory, has convinced me that the popular impression that the skunk-bite in the sections just named is liable to be followed by hydrophobia is a correct one.

Several instances have come under my personal observation, not only where men have been bitten at night while camped on the open prairie, but where the skunk has invaded tents, and even houses, inflicting the deadly bite upon one or more of the sleeping inmates. The poisonous bite is not always given in anger by the skunk, but the animal, searching for food, gnaws the face or hands of the sleeping person.

Between the North Fork of the Canadian and Fort Supply, Indian Territory, I camped one night with an escort near a house occupied by cattlemen. During the night a skunk entered the house and crawled under the bed, where he remained until morning, when he seized a man's leg as he put his foot out of bed; hydrophobia followed the bite in the man.

When travelling with my family by ambulance, and camping on the open prairie, I was very careful to have the sides of the tent well sodded down at night, and at the tent entrance I tied my dog to protect my family from the intrusion of skunks, more dreaded by me than the rattlesnakes.

I think I may safely state that the general impression is, that the bite of the skunk on our Western prairies is, to say the least, very dangerous.

Hydrophobia exists among these pests to a very considerable extent.

The bite of the rattlesnake is, on the other hand, in my experience, not particularly dangerous. Of course, much depends how and when the bite is given by the snake. If his fang-duct is empty, no poison is imparted; if the poison is absorbed by cloth or other absorbing materials before it reaches the wound, then, too, the bite cannot be dangerous. The snake is not always prepared to bite dangerously. For these reasons it is not easy to determine how fatal the rattlesnake bite may be, but it is generally understood by frontiersmen that the rattlesnake of the great prairies is not a very dangerous reptile, and is honest enough to give fair warning before he strikes.

A friend of mine, in an expedition which crossed the plains in 1867, was bitten by a rattlesnake under the following circumstances:

We were camped that afternoon on the Arkansas River. After supper my friend walked outside the camp for a short distance. He had pulled off his cavalry boots and had on a pair of thin slippers. A rattlesnake bit him, as he was descending a little hill, on the inner side of the right foot. My friend deliberately sat down and shot the snake through the head with his six-shooter, and brought the reptile back to camp. The wound was cauterized, and a large dose of whiskey immediately administered. The patient slept that night very soundly in the ambulance, and the next morning was all right, except for the effects of the large doses of whiskey. No trouble followed from poisoning, and the wound healed rapidly. In this case it is possible that either the poison-duct in the snake was empty, or that the leather of the slipper or the stocking prevented the poison from reaching the

wound. Whiskey on the frontier is the remedy *par excellence* for snake-bites, and it is very frequently taken by many as a preventive, and as such is remarkably popular. Very respectfully yours,

W. THORNTON PARKER.

NEWPORT, R. I., February 20, 1886.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 28, 1886, to March 6, 1886.

WILLIAMS, J. W., Major and Surgeon. Ordered for duty as post surgeon, Vancouver Barracks, Wash. Ter. S. O. 31, Department of Colorado, February 20, 1886.

MUNN, C. E., Captain and Assistant Surgeon. Ordered for duty as post surgeon, Fort Cœur d'Alene, I. T. S. O. 31, Department of Colorado, February 20, 1886.

WOOD, M. W., Captain and Assistant Surgeon. Ordered for duty as post surgeon, Fort Walla Walla, Wash. Ter. S. O. 31, Department of Colorado, February 20, 1886.

TREMAINE, WILLIAM S., Major and Surgeon. Leave of absence extended for six months on surgeon's certificate of disability. S. O. 50, A. G. O., March 2, 1886.

MCELDERNY, HENRY, Major and Surgeon. Leave of absence extended for one month. S. O. 49, A. G. O., March 1, 1886.

SPENCER, WILLIAM G., Captain and Assistant Surgeon. Ordered for duty at Fort Yates, Dak. Ter. S. O. 17, Department of Dakota, February 23, 1886.

To be Assistant Surgeons, with the rank of Captain, after five years' service, in accordance with the act of June 23, 1874:

ARTHUR, WILLIAM H., Assistant Surgeon, February 18, 1886. Circular, A. G. O., March 1, 1886.

BUSHNELL, GEORGE E., Assistant Surgeon, February 18, 1886. Circular, A. G. O., March 1, 1886.

BIRMINGHAM, Henry P., Assistant Surgeon, February 18, 1886. Circular, A. G. O., March 1, 1886.

WYETH, MARLBOROUGH C., Assistant Surgeon, February 18, 1886. Circular, A. G. O., March 1, 1886.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 6, 1886:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
March 6, 1886.....	2	8	57	4	4	80	7	0
Deaths.								
March 6, 1886.....	3	3	10	4	0	37	0	0

THE DOSE OF TINCTURE OF NUX VOMICA, according to Dr. Musser, should be from thirty to forty drops for adults from fifteen to forty years of age. Old people should be given smaller amounts.

DEATH FROM EXPOSURE was the verdict recently rendered by a Helena (M. T.) jury on the body of a horse-thief who had been hanged by vigilantes.

DR. MCGILL'S LETTER ON THE HOT-WATER TREATMENT OF WOUNDS.—Dr. Robert T. Morris, of this city, sends a reply to the communication of Dr. McGill in THE MEDICAL RECORD of January 23d, which we are unable for want of space to insert in full. He writes: "Dr. McGill asks for information as follows: 'Where can any modern operator show results equal to those obtained by Alanson in 1779—thirty-five successful cases of capital amputation safely piloted to recovery,' and I would inform him that any work on scientific surgery—Cheyne's, MacCormac's, or Neuber's, for instance—will not only give him statistics of much better work in amputations, but they will show that in all probability the majority of Alanson's amputations were unnecessary operations. Bardenheuer's report (MacCormac's 'Antiseptic Surgery,' p. 29) on the results gained through antiseptic surgery at the College Infirmary in one year runs as follows: Forty-one amputations through bones, 10 amputations at joints, 53 resections, 23 cases of removal of wedge-shaped pieces of bone, 5 operations for badly united fracture, and 1 case of trephining—altogether 133 operations involving bones, without a single death. Cheyne, on page 511 of his work on 'Antiseptic Surgery,' adds together the figures presented by several workers, and shows a list of 1,239 compound fractures treated antiseptically, with but 5 deaths, or less than three-fourths of one per cent. Volkmann reports two deaths among 135 successive compound fractures which he treated antiseptically. One of these deaths was due to delirium tremens, and the other to fat embolism. Schede, at the late Copenhagen Congress, reported 50 successive osteotomies, not done subcutaneously, which healed without the formation of one drop of pus. . . . Here is another quotation from Dr. McGill's letter: 'To some otherwise sane and rational medical scientists Listerism is a veritable *ignis fatuus*.' Mrs. Cadwallader says that we have all to exert ourselves a little to keep sane and to call things by their right names, and it seems to me that *ignis fatuus* is not the right name here, because we have had the thing actually in our possession for several years. Listerism is rather an *ignis fatuus* (if you would accept the term) for the men who have done good travelling in their day, but who are now able to run only in saw-horse fashion. . . . Another part of the letter reads: 'To that famed and most odoriferous drug—that remorseless exterminator of germs—carbolic acid, supernatural powers are attributed.' This is a little mistake on the part of the writer of the letter. The natural power of carbolic acid to kill microbes is like the natural power of salt to kill grass. Nothing more. . . . Speaking of experience at the St. Francis Hospital of Jersey City, Dr. McGill says: 'Listerism had been given a fair trial—the attention to detail so earnestly enjoined by its originator had been faithfully carried out—but the results were not such as would warrant a continuance of its use. Possibly it may have been due to some fault in my use of the method,' etc. If instead of 'possibly' the author had written *undoubtedly*, he would have struck the nail such a blow on the head that the resounding thump could have been heard from Hoboken to Weehawken. That it is hard for some men to comprehend antiseptic doctrines I have no doubt. The trouble arises from our educational methods in medicine, which develop not so many scholarly scientific men as they do artists—artists of the impressionist school particularly. All men who know how to work antiseptically do so."

THE HARVEST BEGINS.—The Buffalo Medical College graduated forty-three students on February 23d.

A NEW JOURNAL, called *Death*, devoted to suicide, homicide, funerals, etc., is, we learn, soon to be published in Chambersburg, Pa. We presume it will be short-lived.

Original Articles.

THE TREATMENT OF VARICOCELE.[1]

By ROBERT F. WEIR, M.D.,

CLINICAL PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS; SURGEON TO THE NEW YORK HOSPITAL.

IT is not intended to present an exhaustive account of the many methods of treatment that have been resorted to in the cure of varicocele, but rather to give in a brief manner the results of personal experience and observation, especially that obtained since the beginning of what may be called the antiseptic era. Prior to this latter period operations for the relief of varicocele were comparatively rarely adopted, and the employment of suspensory bags and other less reliable contrivances was more largely advocated than now. All the operations in the past and present, however, have had as the end in view either to obliterate the distended veins or to shorten the scrotum and thus effect a more complete support.

In the first category comes primarily the plan of Gagneles who was the first, according to Sédillot, to pass a silk ligature subcutaneously across the scrotum in front of the veins and then back again, through the same skin openings, behind them, and thus to encircle the distended vessels in the subsequent ligation. This we all know was a good method, but the material, silk, was faulty and often provoked and kept up suppuration until it either dissolved or was discharged from the punctures. Ricord endeavored to obviate this by his *serre-nœud*, and passed a double-looped silk ligature behind the veins, and another in front and ran the end of one through the loop of the other so that a running reef-knot was formed, which by traction of an outside horse-shoe ratchet cut through the veins and was then extracted. These were the two best methods in vogue, and the evolution of this idea impelled Mr. John Wood, of London, in 1875, to adopt silver wire with spring pressure to cut through the veins or to temporarily constrict them. This instrument, which is herewith shown, did fairly good work; however, its long arm, which afforded the counter pressure to its spring portion, often embedded itself in the scrotal tissues and gave rise to suppuration and abscess, and the ends of the encircling loop of wire emerging from its one opening, as in Gagneles' method, frequently became twisted and prevented its withdrawal when the surgeon desired it. To meet these objections, after using Wood's instrument a few times, I contrived and used for a limited period a little elliptical spring,[2] to straddle the scrotum that it might pull upon loops like Ricord, but of silver wire; and in order to withdraw them before they had cut entirely through (which, with Wood's instrument and this and others of like design, will take place in from ten to fifteen days), the device of the late Dr. Washburne, of this city, was adopted, to have a third wire passed around one of the loops before it was drawn home, to serve as a retractor. This was quite ingenious and serviceable, but recently I found, to illustrate the old adage, that Tufnell,[3] of Dublin, had made the same suggestion some twenty-five years ago. The further use of silver wire as a means of ligating the dilated veins in a varicocele received a decided advance in the method advocated by Barwell, which, though set forth in 1869[4] by this surgeon, attracted more attention since the publication of his article on the same subject in 1875.[5]

Barwell did away with the projecting pieces of mechanism, and thrust the ends of his wire loop, which was passed in the customary manner, through a perforated plate of metal or hard rubber, and tied or twisted the ends fast to little uprights on the outer side of the shield. These wires could be easily tightened from day to day, if deemed advisable. In a very recent article by this surgeon a *résumé* of 100 cases of varicocele thus treated is given. In 16 there was suppuration, in 71 there were no complications. The duration of the treatment is unfortunately not given.

This plan of operation has been followed with quite satisfactory results by my colleague, Dr. Markoe, who, in seven cases treated by him at the New York Hospital, has had suppuration three times, and the average duration of the treatment has been thirteen days. Dr. Markoe also informs me that his larger experience in private practice has been excellent.

But the use of catgut sublimated or junipered as a ligature for varicose veins was the natural outcome of Listerism, and in 1879 I made my first trial[6] of it in the treatment of varicocele, but had soon unsatisfactory results, in two instances having used, with the erroneous idea that such was needed, the chromicized catgut, which in one of these cases failed to dissolve, and after three weeks of suppuration was extracted, and in the second the ligature came out at the end of sixteen days. Since then I have resorted to it in hospital and private practice twenty-two times with generally a satisfactory result. I regret I cannot tell exactly in how many cases suppuration followed, but this occurred from time to time, and especially was it more apt to follow when two or three ligatures were placed around the venous mass, and most particularly was trouble likely to come if the ligature was placed too close to the testicle. Taking it comprehensively, I feel that one is justified as placing this plan of treatment so far, as one of the best, safest, and quickest in its result, and the more so when its application is confined to tolerably small varicoceles—that is to say, where generally one ligature will suffice; in such, twelve in number, the average duration of confinement was eight days. In six out of these twenty-two cases there was dissatisfaction with the results, because either that the symptoms continued, or that other veins increased in volume, or that the undue size of the thickened tissues failed to please. Two of the six, which were all large varicoceles, submitted with advantage to a subsequent ablation of a part of the scrotum.

An anæsthetic has been seldom administered in this catgut ligation of the veins, and then only at the patient's request. The little operation is generally performed with the patient in the erect position, leaning against the edge of a table or bureau, and, after pushing aside the readily felt vas deferens, an ordinary surgeon's needle[4] armed with a strong sublimated or junipered catgut is thrust through the scrotum behind the bunch of veins,

[6] Gurlt-Stromeyer, in the Austrian Medical Journal for December 12, 1885, states that he had similarly used carbolized kangaroo tendon for several years.

[4] Dr. E. L. Keyes recommends [illegible] a curved cutting needle for this

which is then loosened from the grasp, and the needle is then carried back through the same punctures, and more slowly and carefully in front of the veins between them and the skin. If a second ligature is deemed advisable, the first is not tied until the second one is passed. The tying is generally finished with the patient lying down, as then the most pain is felt. After the ends of the ligatures have been cut short, a little pull on the skin of the scrotum will cause the knot on one side and the loop of catgut on the other side to sink out of sight, when the needle-punctures are to be dusted with powdered iodoform and a light antiseptic dressing applied. On the third to sixth day the patient can be allowed to go moderately about with the scrotum in a suspensory bag.

Excision of the veins was promulgated by Patruban in 1870,[1] and revived in 1880 by Nebler, as an excellent method in the treatment of varicocele, and five cases were presented by the latter in illustration of his views. He has been followed by Nicaise [2] who advises, as does Nebler, to carefully separate the artery from the veins, a procedure which not only is not at all easy, but is unnecessary, since the artery accompanying the vas deferens communicates with the spermatic at the entrance into the testicle, though Zesas[3] has shown that this inosculation does not exist in dogs, in whom, therefore, ligature of the spermatic veins with the included artery would cause gangrene of the testicle. Richolot[4] also speaks well of excision, and Reginald Harrison[5] varies the operation a little by tying the larger veins separately through an incision and lightly cauterizing the smaller ones by a Paquelin cautery.

Excision is easiest performed by an incision, under cocaine, one or two inches long on the posterior or lateral surface of the scrotum. When the mass of veins is exposed a double ligature of sublimated or junipered catgut is placed around them, about an inch apart, and the included portion cut away with the scissors. A small drain is inserted and the wound is then closed with catgut sutures and a sublimated gauze or peat dressing applied. If a rubber tube is used for a drain (and this I prefer in all cases) it should be removed on the third to fifth day, and the wound will be found tightly healed at the end of a week. Provided the case has been treated by a surgeon experienced in antiseptic measures, the treatment by excision is both safe and expeditious, and is worthy of adoption, particularly in those cases where the size of the varicocele would demand two or three subcutaneous ligatures or where the more radical operation of scrotal amputation has been declined by the patient. This latter operation, *the removal of the scrotum sufficiently to act as a natural suspensory bandage*, was much in use at the New York Hospital during my pupilage there in 1856 to 1860, and for several years prior and subsequent to that time many cases of cures, and almost as many cases of failures, from its use came, either then or afterward, under my observation. The reason for its desuetude was not difficult to arrive at. Like an elastic suspensory the scrotal tissues gradually yielded to the weight of the enlarged veins which were yet distended, and which varied greatly in their blood contents on any exertion. In other words the principal cause of the symptoms was not removed. This operation was brought again into repute in 1871 by the excellent treatise of Dr. M. H. Henry, of this city, who contrived a serviceable clamp to facilitate its execution. The advent of antiseptic surgery also tended to further the advance of this operation, and meeting with cases in which either failure had occurred from the other methods referred to, and in which the large varicocele was associated with marked elongation of the scrotum, I resumed its use under the stimulus of Dr. Henry's cases. I soon found renewed cause for dissatisfaction, and in 1882 an addition was made to this truncation of the scrotum. This was as follows:

After including the portion of the skin of the scrotum between the jaws of Henry's or Andrews' [1] clamp, which is placed antero-posteriorly along the raphé, to the extreme back limit of the scrotum, and removing the same by a few cuts with a strong scissors, the instrument is removed and all the numerous bleeding points tied with fine catgut. Both testicles are now seen enclosed in their tunica vaginalis, hanging down through the wound, and the dilated tortuous veins are clearly brought into view. Instead of closing the wound, after washing it with the sublimate solution of 1 to 2,000 or 1 to 5,000, I determined, and so did then and since, to tie these veins while thus exposed in one or two selected places, by passing a catgut ligature around them, which is a matter of very easy accomplishment.

I soon found an extra reason to be pleased with this method. In not a small number of varicoceles there is associated with them the formation of little spermatic cysts about the head of the epididymis, which are often the seat of considerable pain. These when encountered in an amputation of the scrotum, can not only be very easily recognized but treated. They are simply to be split open and their interior swabbed out with pure carbolic acid, applied on a cotton probe or match. The temptation is great to tie all the sets of varicosed veins, and there are generally two, and sometimes three packets of such to be seen. The larger one or ones contain the spermatic artery. I have attempted but once to isolate this, so as to tie only the veins, and found it then impracticable, and the testimony of others is in the same direction. This care is unnecessary, as has been already stated, but it would be dangerous to ligate the artery of the vas deferens. This is to be found in the smaller detached batch of veins that inclines toward the base of the testicle. These are therefore not to be tied; at least, in the only case in which I know of risk occurring to the testicle the ligatures were so placed, I understand, as to choke off all the veins.

If care is taken to arrest all oozing of blood, the wound may be closed with interrupted or continued catgut sutures (the former are preferred) without using a drainage-tube, and a dressing of peat-bags or sublimated gauze, over the surface of which iodoform is dusted, can be applied, and firmly secured in place, over layers of absorbent cotton, by a tight double figure-of-eight bandage. By doing in this manner primary union is obtained in from five to eight days. If the bleeding is not entirely checked, a drainage-tube should be used and removed on or before the fifth day. It is needless to say, that in all the surgical interferences with the scrotal veins, from simple ligation to amputation of the scrotum, strict attention to antiseptic rules should be maintained.

Should, in either of the cutting operations, failure of union occur, the granulating patch is quite painless and does not prevent the patient going about with a large cotton-lined suspensory bandage.

I have now repeated this operation for large or otherwise intractable varicocele in nine cases, and with a most satisfactory result, and without any complication in the treatment save such as came in a few instances from the premature giving way of several turns of a continued suture, and it is for this reason that the interrupted suture is now advised. Dr. Abbe, one of the surgeons at St. Luke's Hospital, has also had six cases in which this treatment has been applied, with an excellent result, and in two of these the operation was painlessly done by him under the subcutaneous injection of cocaine.

Whether the procedure has exactly been used by other surgeons is not known, but it is extremely probable that it has, for the end to be attained has existed in the mind of the distinguished Guyon,[2] for instance, who, in 1884,

reported several cases where he successfully amputated the scrotum for varicocele by a transverse cut and tied the veins in the wound, and Henry Lee,[1] of London, advocated, in 1885, the radical cure of varicocele by scrotal amputation and subsequent temporary ligation of the veins until they have been divided and their ends lightly seared with a black cautery iron, on the ground that in the severer cases of this disease other operations are but temporary in their benefit.

Since my experience does not proceed beyond the operations recorded in the foregoing remarks, I beg forthwith to sum up in these concluding words: 1. That for small varicoceles, there is nothing better than the single (or double) subcutaneous catgut ligature. 2. That for medium-sized varicoceles or for cases declining a more heroic operation, excision in careful hands is to be advised. 3. That for large varicoceles, for relapsed cases, and for those not very large, but with a much elongated scrotum, ablation of the scrotum with ligation of the veins is preferable.

A CONTRIBUTION TO THE NATURAL HISTORY OF PULMONARY CONSUMPTION.

Embracing the Causation and Symptomatic Events. Based on an Analysis of Fifty-nine Cases of the Disease.

By JAMES KING CROOK, M.D.,

Assistant to Dr. Arthur Nicholls in Mount Sinai Hospital Dispensary, Fellow of the New York Academy of Medicine, and Physician to the Out-Door Department of the Presbyterian Hospital.

Continued from last page.

Infection and contagion.—It does not come within the scope of this paper to discuss this important and somewhat perplexing subject at length. A brief retrospect of some of the cardinal points in its literature may, however, not be out of place.

The doctrine of the infectious or contagious nature of pulmonary consumption has always had an extensive following in the South of Europe. Galen was a believer in this doctrine, and Morgagni firmly advocated it. It received but little attention, however, from the great body of the medical profession until M. Villemin succeeded in 1865 in inoculating rabbits with the virus of tuberculosis.[2] Research in this line of study at once received a great impetus, which has continued to the present day without abatement.[3] Villemin's experiments have been repeated and confirmed with more or less exactness by various investigators (Clark, Fox, Sanderson, Tappeiner, Schottelius, Gerlach, Cohnheim, and others). Some of these observers, however, found that the employment of other substances, such as cinnabar, cork, cheese, pulverized brain-tissue, the sputa of simple bronchitis, etc., led to apparently the same result as the introduction of the true tuberculous virus. The more recent elaborate experimental investigations of Hyppolite Martin prove that tubercular material alone is capable of reproducing true tubercular lesions, and that the so-called tubercular reproductions of other foreign substances are not genuine, but "pseudo-tubercular" lesions.[4]

In the light of these prognostic events, the announcement by Robert Koch[5] of his discovery of the *bacillus tuberculosis* was not altogether unlooked for. This chain of experimental research points very strongly to the presence of a specific and contagious virus in the lesions of tuberculosis, of which the micro-organism of Koch seems to be the essence. So far as I know only two instances of direct inoculation from man to man are on record. Though standing alone they are yet of great importance. Following is a brief sketch of these cases. 1. Three Greek physicians of Syra inoculated a patient with perfectly healthy lungs, who was in a moribund condition from gangrene of the left lower extremity, with the sputum of a phthisical patient. Signs of induration appeared at the right pulmonary apex at the end of three weeks, and in thirty-eight days the patient died of the gangrene. At the necropsy seventeen small tubercles were found at the right apex, varying in size from a mustard-seed to a lentil. Two granulations were also found at the left apex, and two on the convex surface of the liver.[1] 2. A cook, a sound, healthy woman, in the family of Professor H——, in removing a cup containing sputa from the bedside of the professor (who was suffering with consumption, and died soon after), cut her hand on the vessel, a spicula of glass puncturing one of her fingers. The injured member refused to heal, and the cubital and axillary glands became swollen and indurated. The finger was disarticulated, and the enlarged glands also removed. Specimens, both of the finger and the extirpated glands, were prepared, and a microscopical examination demonstrated the presence of tubercular bacilli in abundance.[2]

The foregoing data constitute our chief reasons for regarding pulmonary consumption as an infectious or contagious disease. Some of the facts are very suggestive, but much remains to be explained. Isolated cases are reported from time to time, which seem to have their origin in contagion. It has not been shown, however, why years of exposure to, and attendance on, phthisical cases, examples of which we see daily in hospital nurses and attendants, fail to develop the disease. The great mass of clinical experience is at variance with the doctrine of contagion or infection. An analysis of the cases in the table which form the basis of this paper fails to offer it much support. All of the patients were interrogated as to opportunities for contracting the disease through contact with, or living with, other consumptive patients. It was ascertained that 12 of the patients were at the time, or had recently been, living with or nursing a consumptive relative. In 3 instances the patients stated that they slept in the same bed, and in 5 others in the same room. It will be seen by consulting the table, however, that the person lived with was in almost every case a near blood-relative; hence, it is problematical whether family predisposition, or a common mode of life, were not equally as, or more, instrumental in determining the development of the disease than the medium of personal contact. Some of the patients informed me that they had never, to their knowledge, seen a person who was suffering with consumption.

After a careful review of this much-vexed question, it strikes me that the present state of professional opinion may be formulated as follows: First, the results of *experimental pathology* are strongly in favor of the proposition (*a*) that tubercle is an infectious malady originating in a specific virus and propagated by the conveyance of that virus from body to body, and originating in no other way; and (*b*) that the activity of this virus is embodied in a micro-organism peculiar to tubercle and denominated by Koch the *Bacillus tuberculosis*.[3] Second, *clinical experience* fails to sustain this view. It shows that while consumption may possibly be communicated from person to person by long and constant contact, especially in cases in which the *receptivity* already exists,

[3] An admirable exposition of the [illegible] may be found in Friedlander's Manual of Microscopical Technology, translated by Dr. Stephen Yates Howell, New York, 1886.

the vast majority of cases originate from causes entirely independent of this influence, so far as can be traced.

Pregnancy, childbirth, miscarriage, etc.—Of the 19 female cases analyzed, 16 were married, 12 had been pregnant, and 5 of the 12 had had one or more miscarriages. Two of the patients had a vague idea that childbirth or nursing had something to do with bringing on their disease, but the connection seemed very remote and this is not given a place among the causes assigned by patients in the table. One patient, however, dated her disease very clearly from a miscarriage which she had had a few months previously. It was attended by great loss of blood and several weeks' confinement. She developed a cough during her illness which was soon followed by hæmoptysis, night-sweats, and emaciation. On her visit to the clinic she was well advanced in consumption, having catarrh at the left apex and extensive consolidation in the upper part of the right lung. There was no hereditary influence in this case, and the connection between the miscarriage and the lung trouble seemed very direct. In none of the other cases, however, did it seem reasonable to attach any etiological significance to the fact that the patient had borne children or had miscarriages. Altogether these cases do not offer much support to the view that pregnancy or childbirth bear an important causal relation to phthisis. It has been clearly established that consumption is more common among males (at least in the class among whom these observations were made) than among females. The inference does not seem illogical that if those influences to which males are not subject were largely operative, such would not be the case. Besides, it must be remembered that a large proportion of women marry and bear children, so that phthisis must necessarily choose a considerable number of its victims from this class. In this connection an interesting point of investigation relates to the relative frequency of consumption in the two sexes during the fifth decennial period of life, as during this decade the vast majority of women attain the menopause, or "critical period." An analysis of the 917 cases shows that 96 out of 548 males, or a little more than seventeen per cent. were between forty and fifty years of age, and that 57 out of 369 females, or only a little more than fifteen per cent., were of the same age. It may be stated that several of the females attributed more or less influence to "change of life" in bringing on their lung disease. It is well known, however, that any illness, of whatever nature, which may occur about this period, is apt to be referred by the patient to the same cause. No other reason than that the age for change of life had come was assigned for their suppositions in these cases, and it seemed to me that the occurrence of phthisis was coincidental and not referable to the menopause. A study of the foregoing facts, then, would oppose the view that the functions peculiar to the female sex, or the cessation of those functions, are largely instrumental in the production of consumption.

Alcoholics.—Fifty-five of the cases in the table were interrogated as to their habits with regard to the use of alcoholic stimulants. The following results were obtained: 9 patients admitted that they were habitual hard drinkers; 26 were addicted to the use of alcoholic stimulants in moderate quantities, and 4 drank occasionally; in all, then, 39 patients out of 55 who were questioned were more or less habituated to the use of alcoholic beverages. These facts would seem to contravene a very popular idea that such indulgence acts somewhat in the nature of a prophylactic against consumption. However beneficial their judicious use may be in the treatment, it can not be said that the ordinary habit of alcoholic indulgence offers much in the way of prevention of the disease.

Syphilis.—The subject of the relationship between syphilis and pulmonary disease is one which has attracted considerable attention in this city during the past few months, and about which no little difference of opinion still exists. Hence, in investigating the influence of syphilis in these cases every precaution was taken to avoid error and to secure truthful histories, in order, if possible, to obtain an insight into the real condition of affairs. The impossibility of ascertaining the influence of heredity with respect to syphilis under the circumstances attending these investigations is evident. The following account, therefore, and the conclusions deduced therefrom, relate only to acquired syphilis. In 5 of the 59 cases, for sufficient reasons, no questions were asked on this subject. In the remaining 54 cases the results of a close and careful examination were as follows: 40 of the patients stated positively and unequivocally, that they had never at any period of their lives had a sore or ulcer of any nature whatever upon their genital organs. They also gave negative replies when questioned with reference to the common well-known symptoms of secondary syphilis. None of these patients had, so far as I could ascertain, any symptom or sign of syphilis at the time of examination. Four of the patients gave histories which made the existence of syphilis at some past time probable, or at least suspicious. Subjoined is a synopsis of these cases:

Case. 1.—A widow, aged forty-five, whose husband had died many years previously. She admitted that she had been exposed to venereal contact since that time and was under the impression that she had had syphilis ten years previously to the time she came under observation. She remembered no symptoms, however, except a skin disease, and is classed in the table as "suspicious." She had lost her mother and a son with consumption, and attributed her lung disease to exposure to cold and wet. She had slight periosteal tenderness and a cicatrix on the left side of her neck, whence an enlarged suppurating gland had been removed.

Case 2.—A widow, aged forty-two, a professional equestrienne, who had led a fast life. She stated that her husband had syphilis before he died and that about twenty years ago (prior to examination) she had had a suppurating ulcer on the left labium majus. The sore soon healed and was not followed by any secondary symptoms that she remembered. She had lost a sister with consumption. The patient thought her lung trouble was due to "change of life," although she had not been entirely well since an attack of pleuro-pneumonia, which she had in April, 1884.

Case 3.—An old man, aged sixty-five, who had travelled over the world considerably and thought that he had had all the venereal diseases "known to science." I could get no history pointing to syphilis, however, except of "swelling in the groins," and he too is classed as "suspicious." He thought that his lung trouble was the result of a general breaking up of his system due to old age.

Case 4.—A woman, aged thirty-seven, who thought she had contracted a blood-disease from her husband, who the doctors said had syphilis several years ago. She had a rash on her skin which lasted a month or two, and some soreness of the throat, but no local sore. She attributed her pulmonary disease to mental anxiety, caused by domestic troubles. She had well marked hydrothorax in addition to her phthisical trouble.

Basing the diagnosis of syphilis on the presence of a local sore followed by secondary symptoms, we find that ten out of fifty-four cases (about eighteen per cent.) gave tolerably clear histories. Reference to the table will show the leading points in connection with these cases, so that it will be unnecessary to repeat them here. It should be mentioned, however, that in two cases of long-standing phthisis the patients informed me that they had well-marked symptoms of lung disease before contracting syphilis. In three others, also, the local sore described was not of the indurated, non-suppurating variety, commonly known as the initial lesion of syphilis. The manifestations of tertiary syphilis were also very

meagre in most of these cases. Only four had alopecia, less than half a dozen made complaint of osteocopic pains, and in only five of the entire fifty-nine was there any lesion of the skin whatever at the time of examination (one of these cases was afterward diagnosed as psoriasis by a competent dermatologist).

Tenderness and œdema over the sternum and tibial crests has been urged by Professor William H. Porter[1] as a pathognomonic sign of advanced pulmonary syphilis. As described by Dr. Porter "pressure over these regions produces a very peculiar pain which is quite intense and accompanied by a recoil not easily forgotten when once recognized. Patients often try to avoid giving evidence of this, but as surely fail as though trying to resist the muscular reaction of the electric current." Being aware of Dr. Porter's views on this subject early in the summer (before the publication of his paper), I determined to give it a careful investigation in every case of phthisis which should come under my observation during the session. Fifty-seven of the cases in the table were examined with reference to this sign. The result was as follows: In five cases, more or less evidence of pain could be elicited by making firm pressure both up and down the sternum and the crests of the tibiæ. In no case, however, was the pain unendurable, or even extremely severe. In the remaining fifty-two cases all endeavors to bring out this sign were futile. Every precaution was observed, the patients often being taken off their guard, but nothing further than the necessary discomfort produced, which bore no semblance to pain, was complained of.[2] Some significance, however, may lie in the fact that three of the five cases in which periosteal tenderness was present had syphilitic histories, and a fourth gave a history suspicious of syphilis. In looking for a possible connection between the syphilitic symptoms and the development of consumption meagre results were also obtained. We find that two of the patients with histories of syphilis had had pneumonia; three had had pleurisy; the father of one had died with consumption, and two were living with consumptive brothers. Altogether, then, eight of the ten gave efficient causes for phthisis without taking the syphilitic histories into consideration. Again, in looking over the events of the histories of the syphilitic cases as shown in the table, it is difficult to see wherein they differ from those in the cases without syphilitic histories. We find the familiar cough, hæmoptysis, night-sweats, emaciation, dyspnœa, elevation of temperature, etc., in about the same proportions in both classes of cases. A careful study of the foregoing facts warrants us in assuming from a *clinical* point of view, first, that syphilis is not a cogent factor in the production of pulmonary phthisis; second, that the fact that a patient has had syphilis modifies to a very slight, if to any extent, the ordinary course of a phthisical attack.

Rheumatism.—Articular rheumatism has been mentioned from time to time as having a causative relation to phthisis. On examining the 59 tabulated cases we find that 6, or a trifle more than ten per cent., gave rheumatic histories; 13 others stated that they had had rheumatism, but on careful questioning it was found that their trouble had been muscular rheumatism (lumbago, pleurodynia, scapulodynia, etc.), or dorso-intercostal neuralgia. Their influence in the causation of phthisis may probably be regarded as *nil*. The remaining cases had had neither muscular nor articular rheumatism. Following is a brief sketch of the cases with rheumatic histories:

Case 1.—Male, aged forty-seven. Had several attacks of articular rheumatism which he thought undermined his health. He did not date his pulmonary symptoms from an attack, however, as he had been up and about for six or eight months when he commenced to cough.

Case 2.—Male, aged twenty-eight. Had an attack of rheumatism eight or nine years ago, about a year and a half before the commencement of pulmonary symptoms. His joints remained stiff and sore for a long time.

Case 3.—Male, aged thirty-seven. Had rheumatism ten years ago, with complete recovery. Symptoms of consumption came on three or four months ago. He had subacute pleurisy, complicating his phthisis.

Case 4.—Female, aged forty-three. Had several attacks of rheumatism in her joints, and felt touches of it to date of examination. This patient had lost a sister with consumption, and had had several miscarriages. She attributed her disease (consumption) to exposure.

Case 5.—Male, aged twenty-seven. Had rheumatism fourteen years ago, and entirely recovered. Phthisis commenced in December, 1884 (about eight months before examination). Father died of consumption.

Case 6.—Male, aged thirty. Had rheumatism nine years ago, with perfect recovery. This patient dated his consumption from an attack of pleurisy which he had in 1884.

The histories of these cases do not show an intimate relationship between articular rheumatism and consumption, and offer no support to the view that the former is an active cause of the latter. It is not unreasonable to suppose, however, that severe or repeated attacks of rheumatism may so debilitate the system as to render it less capable of withstanding the exciting causes of consumption.

Pneumonia and pleurisy.—Of the 59 tabulated cases, 10 stated that they had had pneumonia, 9 had had pleurisy, and 4 had had both diseases[1]—in all 23 cases, or almost thirty-nine per cent. of the whole number. Seven of the patients dated their present illness directly from a pneumonic attack, having never recovered from its effects, 2 from an attack of pneumonia and pleurisy combined, and 1 from a pleuritic attack, making in all 10 cases, or seventeen per cent. in which the connection between the antecedent pulmonary disease and the symptoms of consumption were clear and unmistakable. In most of the remaining cases the patients attached great importance to the previous lung trouble, stating that they had never been as strong as before, that they considered the lung on the affected side weak, etc. A physical examination almost invariably showed that the phthisical process was situated on this side or on both sides. We find that 6 of these patients gave a family history of consumption, which leaves 17 cases, or 28.8 per cent. of the whole number, in which antecedent pulmonary disease seemed to be the most efficient factor in the development of the phthisical attack. These cases would indicate that pneumonia and pleurisy possess a very strong etiological relation to consumption.[2]

Other antecedent diseases.—In order to learn the influence of other affections in the development of consumption, each patient was interrogated as to what diseases, if any (besides those already considered), he had suffered from during the three years immediately preceding the appearance of the phthisical symptoms. The subjoined result was obtained, for which, of course, due allowances must be made for forgetfulness, etc.: Malarial fever, 3; tape-worm, 3; dyspepsia, 2; gonorrhœa, 2; and 1 each of the following—enteric fever, hæmorrhoids, colliquative diarrhœa, chagres fever, prolapsus uteri, "uterine disorder," habitual constipation, severe bronchitis, diphtheria, hæmatemesis, heart dis-

[1] New York Medical Journal, August 1, 1885. In this paper Dr. Porter states that fifty per cent. of all cases of pulmonary disease treated at his clinics could be traced to a syphilitic origin.

[2] In upward of 1,000 cases of various diseases of all kinds which I have seen at the clinics of Professor Burt since October, 1883, I recall less than a dozen who complained of unusual pain while undergoing the ordinary manipulations of a physical examination. Since reading the paper of Dr. E. Darwin Hudson, Jr. (Medical Record, 1885, xxvii., 505, 510), I have seen several cases in which the muscular tumor or "cutaneous intumescence" described by him could be produced by light, immediate percussion-blows over the costal cartilages in thin subjects.

[1] These diagnoses, I was informed by the patients, were made at the time by the attending physicians.

[2] Professor Ruehle is of the opinion that pleurisy acts chiefly as an exciting cause in cases in which a diathesis already exists (Ziemssen's Cyclopædia, vol. v., p. 501).

ease, abdominal neuralgia, nasal catarrh, emphysema, and hydrothorax. Some of these affections continued up to the time the patients came under observation, and will be further considered under the head of Complications. As will be seen, many of them are of minor importance, and none occurred with sufficient frequency—with the possible exception of malarial fever—to give them any special causative significance. Two of the patients stated that the knowledge of having a tape-worm gave them constant anxiety, and this no doubt exerted a deleterious influence over the pulmonary trouble. We may say, then, that this point of enquiry produced, on the whole, rather negative results.

Climate; where living when symptoms appeared, etc.—The object of this point of enquiry was to ascertain as far as possible the effect of the climate of New York on the production and course of consumption. The number of cases observed was too small and the visits of the patients too irregular to lead to decided results. As might be expected, most of the patients developed their disease in New York, their place of residence. Following is a list of the places or countries where the symptoms of phthisis first made their appearance: New York City and vicinity, fifty-two, and Germany, Malta, Pennsylvania, Nebraska, Chicago, and Philadelphia each one. Both the patients from the West—one from Nebraska, the other from Chicago—considered themselves very much worse since their arrival in New York. The Chicago patient informed me that his symptoms had almost disappeared and he supposed he was getting well while in the West, but since his residence in New York (only a few weeks) he was much worse than ever. His disease was rapidly progressive during the time he was under observation. These limited observations only corroborate a fact which is already well-known, viz., that the climate of the seaboard in this latitude is highly favorable to the development and rapid progress of phthisis pulmonalis.[1]

Influence of season.—All the patients were interrogated on this subject in order to learn at what period of the year phthisis is most likely to be developed. In 16 cases the patients were unable to state this point. The remaining 43 cases began as follows: In January, 6; February, 3; March, 5; April, 3; May, 1; spring (month unknown), 7; June, 4; July, 4; August, 3; September, 1; October, 1; December, 5. Thus we find that in the three winter months (December, January, and February) the symptoms came on in 14 cases, in the spring in 16 cases, in the summer in 11 cases, and in the fall in 2 cases. This gives a slight percentage in favor of spring, which is closely followed, however, by winter. The fall months show a strikingly small proportion, November not being represented at all.

At the Bellevue Dispensary cases of consumption are considerably more frequent in the winter and spring than in the summer season. This may be partially accounted for by the fact that some of the patients under treatment secure employment in the country, or, at any rate, leave the city at the advent of hot weather. Nevertheless, it cannot be doubted that some of the prolific causes of phthisis, viz., pneumonia and pleurisy, are far more frequent in winter and spring than in the summer.

Floor of house occupied.—It did not occur to me to enquire into this subject until late in the summer, consequently I obtained statistics of only twenty cases. The question, On what floor of the house were you living at the time your symptoms first came on? was asked in each case. The result was as follows: 10 occupied the first floor, 5 the second, 1 the third, 2 the fourth, and 2 the "top" floor. (Almost without exception the patients lived in tenement houses.) Thus we see that one-half of the patients interrogated lived on the lower floor, and a fourth on the floor next above. The number analyzed, to be sure, was not large, and a more extensive enquiry might lead to different results; but so far as they go these cases show that persons living on the lower floors of New York tenement houses are much more liable to consumption than those on the upper floors. This is not surprising to those who are acquainted with the construction and surroundings of these places of abode; the upper floors as a rule have better facilities both for light and ventilation than the lower.

Causes assigned by patient.—In order to complete the enquiry into the causation, each patient was asked to give his own opinion as to the most probable cause of his lung trouble, or to what facts or events he attributed it. Eighteen of the patients were unable to assign a cause; forty-one, however, had opinions on the subject, and not a few very positive convictions.

The results of this enquiry were as follows: Inherited, or because it was in the family, 4; heredity and exposure, 1; result of pneumonia, 6; result of pleurisy, 1; of pleurisy and syphilis, 1; of pleurisy and subsequent exposure, 1; result simply of exposure, 7; hard work, 3; occupation, 3; "change of life," 3; bad cold, 2; close confinement, 2; bad air, 2; "hard luck," 1; domestic troubles, 1; old age, 1; contracted while nursing consumptive aunt, 1, and ill-treatment, miscarriage, and hard work, 1.

Some of these causes are perhaps a little far-fetched, but it cannot be doubted that in most cases the patients were very near the truth.

Facts Pertaining to Symptomatology.—In inquiring into this subject, we will first consider the symptom or event which initiated the disease. In 15 of the cases the first symptom noted by the patient was a dry cough: Commenced with cough (character not stated), 15; with hæmoptysis, 8; cough and hæmoptysis together, 2; pneumonia, 6; pleurisy and pneumonia (pleuro-pneumonia?), 2; pleurisy, 1; pain in side, 2; pain about heart (mitral regurgitation), 1; "bad cold," 1; attack of bronchitis, 2; intermittent fever, 1; vertigo and sick stomach, 1; and suppressed menstruation, 1. One patient did not remember how his trouble began. Pneumonia and pleurisy have already been discussed; the other principal symptoms will be considered under their individual heads.

Cough and expectoration.—As would naturally be expected we find cough to be the most constant and one of the most prominent symptoms. This event initiated the disease, or, at least, was the first symptom observed by the patient in 30, or more than half the cases, without considering those beginning with pneumonia or pleurisy. Fifteen of these stated that the cough was dry and hacking in the beginning, while in 15 others the character of the initiatory cough was not noted. Two of the patients informed me that they had been treated a long time for bronchitis before they commenced to have night-sweats, hæmoptysis, and other common symptoms of consumption. In all the other cases, however, the patients considered the cough a part of the disease, *ab initio*.[1] In only one case of the 59 was this symptom absent. This patient, a female aged thirty-four, persistently maintained that she had no cough at the time these observations were made, nor had she ever had any, although her history extended over a period of several years. Yet we find that she had great emaciation, pallor, dyspnœa, disordered digestion, aversion to fats, night-sweats, and scanty menstruation. On physical examination, bronchial breathing and dulness showed extensive consolidation in the upper part of the right lung. The patient informed me that she raised more or less yellowish or sanguineous expectoration at times, but that no efforts at coughing were required. Accepting the statement of the patient as true, this condition would seem to admit

[1] For valuable remarks on this subject see Curnow, J. Kay, M.D., etc., in Gaillard's Medical Journal, November, 1881, and January, 1882. According to Blodgett's Climatology the percentage of deaths from phthisis in New York [illegible] (reports) that the percentage of deaths from this disease in the United States diminishes progressively from North to South. For example, in Maine it is 258; New York, [illegible] Mississippi, [illegible] whole United States it is 142 per 1,000.

[1] It is probable that many of the cases, especially those resulting from exposure, "bad cold," etc., began as simple bronchitis.

of no explanation, save under the hypothesis that there was complete loss of sensibility of the laryngeal mucous membrane.[1] With reference to *expectoration* we find that it was variable in 9 cases, profuse or abundant in 28, and variously denominated as scanty, bloody, or frothy in 18. One patient stated that he had never had any expectoration, and in 3 no inquiry was made in regard to it. The nature of the expectorated matters was observed, so far as possible, while the patients were in the clinic-rooms. In general, it was found that the expectoration was more abundant in advanced cases, and in cases that were progressive, though not a few exceptions to this rule, were noted.

Dyspnœa.—This symptom was present with greater or less severity in 50 cases; 8 of the patients stated that they had never experienced any shortness of breath, and in one case no inquiry was made. In several cases the dyspnœa seemed to be more the result of general weakness than of destruction of the respiratory surface. Generally speaking, however, it seemed to bear a tolerably constant relation to the progressiveness of the disease, and to the extent of lung-tissue involved.

Hæmoptysis.—In the table we find that this symptom existed in 43 cases, was absent in 14, and was not noted in 2. In 31 additional cases in which enquiries were made it was present in 22 and absent in 9 cases. This makes a total of 65 cases in which hemorrhage from the lungs was present out of 88 which were noted. Three of the cases in the table came under observation during the summer suffering from this symptom alone, having no physical signs whatever at first. They developed consumption while under observation, as shown by the gradual appearance of other symptoms and by repeated physical examinations of the lungs. We find on examining the table that in 8 cases hæmoptysis was the initiatory symptom, and in two others either the first or second. Whether or not the occurrence of bronchial hemorrhage acts as an exciting cause of phthisis is by no means a settled question;[2] it is very generally recognized as an extremely significant prodromic event. My observations lead me to believe that, occurring at any time, it should not be lightly regarded. Aside from the local irritating effects of the effused blood, and from the loss to the general system, it excites apprehensions in the mind of the patient from which it is difficult to reassure him, and undoubtedly in this way exerts a very unfavorable influence on the progress of the disease.

Pallor.—Of the 59 cases analyzed, 50 exhibited more or less pallor of the surface. This symptom was generally found to follow a course *pari passu* with the emaciation. A few exceptions were noted in which great pallor was present with very slight loss of flesh, and *vice versâ*. In 2 cases, which are marked "fibrous phthisis" in the table, the superficies presented a florid aspect, and in several other cases the face was not notably pale. *Brilliancy of the eyes* was observed in the majority of recent cases in patients under the age of thirty, though facts with reference to its frequency are not embraced in the records. This symptom was usually concomitant with high temperature. In spite of the few exceptions noted, pallor of the surface may be classed as one of the most constant signs of consumption, and probably no case runs its course without it sooner or later.

Emaciation.—This symptom was noted in all the tabulated, and in 33 additional cases, making a total of 92. It was present to a greater or less extent in 88. In 4 cases the patients stated that they had not lost in weight since the beginning of the phthisical symptoms. Variation in the weight was noticed to be one of the most reliable indices to the progress of the disease. When the patient was not losing flesh the other symptoms were apt to be in abeyance, but when the reverse was the case the phthisical processes were found to be steadily extending.

Pain.—Twenty-six cases stated that they had experienced no pain whatever since the beginning of their lung trouble. Thirty-three had pains of various kinds in the region of the chest. In most of these the pain referred to was found to be wandering, fugitive, muscular, or præcordial, being largely due to intercostal neuralgia or pleurodynia, and occasionally to violent coughing. It was not uncommon to find the pain on the opposite side or in a situation remote from the seat of the disease. In only six or seven cases could it be traced to the diseased lung, and even then it bore no relation to the severity or progressiveness of the disease. From these data, then, it would appear that pain is not a prominent event in the history of consumption, and that it is of little importance in making a diagnosis, either of the existence or of the location of a phthisical process.

Sternal and tibial dulness and tenderness.—This subject has been considered under the head of Syphilis.

Night-sweats.—This symptom was present in 49 and absent in 10 of the tabulated cases; in 27 previous cases it was present in 24 and absent in 3 cases. Most of the cases in which it was absent were in an advanced stage. Several of these informed me that they had had night-sweats several months, or a "long time," ago, but others insisted that they had never had them.

Erasmus Wilson was, no doubt, correct, when he affirmed that the skin acted as an "everted lung" in eliminating carbonic acid, and thereby ventilating the blood, for we cannot question its use as an emunctory in health; but the theory that the night-sweats of phthisis constitute a conservative process on the part of nature in aiding a crippled lung, and that they are thereby beneficial to the patient and deserving of encouragement, meets with no support from the cases which I have seen. The patients invariably informed me that, aside from the discomfort produced, they felt weaker, less cheerful, and worse in all respects after a severe night-sweat.

The few exceptions noted do not invalidate the general rule that night-sweats constitute one of the most constant, as well as debilitating and distressing, symptoms of phthisis.

Appetite, digestion, etc.—Twenty-two of the 59 patients had good or fair appetites. In 36 the appetite was indifferent, poor, or altogether absent. One patient spoke of having "peculiar cravings" since the beginning of her disease. She constantly longed for such articles as pickles, sauces, etc., which she had never relished while in health. Twenty-four of the patients stated that they considered their *digestion* good or fair; 34 made complaints of certain errors of digestion, 14 of this number were costive and 4 had diarrhœa almost constantly; five of the number had frequent spells of vomiting, and 11 complained of pains after eating, and eructations, nausea, and occasional constipation, or diarrhœa. One case was not interrogated on this point.

In regard to *fatty articles of food*, 18 patients stated that they had always had a distaste for them. The appetites of 18 others had changed in this respect since the beginning of their disease (about thirty-two per cent. of those observed). They formerly relished such articles, but could not now eat them without nausea or vomiting. Twenty of the patients relished fats, or could eat them without disagreeable effects. Three cases were not noted. *The tongue* was considerably or heavily coated in 41 cases, slightly coated in 8, clear in 6, and not observed in 4 cases. Coating of the tongue would appear, then, to be a very constant condition in consumption. It was observed in a number of cases, who stated that the appetite was good, the bowels regular, and who seemed to have no trouble with digestion. It was certainly far more frequently observed in the cases of con-

[1] In the Medical Times and Gazette of April 1, 1882, two cases of [illegible] reported in which expectoration was absent throughout the course of the disease, and the cough was so slight and infrequent as to pass almost unnoticed. The downward course was rapid, death occurring in each case in [illegible] month, and the other symptoms and physical signs were not different from those of ordinary phthisis.

[2] Drs. Reginald Thompson and William Ewart are of the opinion that a large proportion of well-defined encapsulated cavities take their origin in hemorrhagic deposits (Ewart-Gulstonian Lectures for 1882, Brit. Med. Journal, 1882, i., 333 *et seq.*).

sumption than in cases of asthma, bronchitis, emphysema, and other pulmonary troubles which came under my observation.

Bulbous fingers and incurvated nails.—Fifty-eight of the tabulated cases were examined for these conditions. It was deemed that 25 (slightly more than forty-three per cent.) of this number had one or both.[1] In only two or three instances, however, were they so well marked as to have attracted the notice of the patients, most of them asseverating that no changes had taken place in the shapes of their fingers or nails since the beginning of their illness, and that these appearances were due to rough usage of their hands by hard work, etc. This was doubtless true to some extent, for the same appearances were observed in patients who had no trouble with their heart or lungs. It will be seen, too, that a number of the cases in which these conditions are noted as existing that the patients were in the early stages of the disease; on the contrary, some of the far-advanced cases showed no signs of them. On the whole, then, these data would indicate that clubbing of the fingers and incurvation of the nails are signs of only occasional value in the diagnosis of phthisis, and that their existence should be given very little weight when occurring among the laboring classes.

Œdema of the feet and ankles.—Dropsy of the lower extremities was entirely absent in 41 cases out of 57 who were examined. It existed in 16 cases, but was very slight in most of them. In only 3 was it well marked; one of these was complicated by mitral regurgitation, and hydro-thorax and hydro-peritoneum. A majority of the patients were examined at an hour when œdema of the lower extremities should manifest itself if the conditions were present for its existence, viz., from 1:30 to 2:30 P.M., after they had presumably been on their feet a number of hours. As far as they go, the foregoing numerical facts would indicate that dropsy of the feet and ankles is not a sign of much importance in "walking cases" of consumption.

Mental condition.—Twenty of the 59 cases were cheerful and hopeful, 2 felt indifferent, 31 were depressed or low-spirited, and 6 said that their state of mind with regard to their disease varied—sometimes they felt hopeful, even buoyant, at others very low-spirited. In none of the cases did the state of mind seem to bear much reference either to the stage of the disease or to the progress it was making. Some of the patients, even in the earliest stages, and in cases in which the disease was making very little if any progress, were in a state of great despondency—a marked contrast to the cheerful, buoyant frame of mind in which I found some of the most advanced cases. The mental condition seemed to bear a much more constant relation to the intellectual constitution of the patient than to his physical state.

Menstruation.—Of the 19 female patients in the table 10 stated that menstruation had ceased altogether since the appearance of the symptoms of consumption; in one of these, indeed, arrest of the menstrual flow was the first intimation the patient had of her approaching illness. In all the others it came on early, becoming scanty and irregular, and soon ceasing altogether. Menstruation is noted as being scanty, irregular, or diminished in 3 others. Five of the patients were past the menopause, while one claimed to be nursing a child to which she had given birth a few months previously. These results corroborate those of previous observers, viz., that arrest or irregularity of the menstrual function is an early and constant symptom in women afflicted with phthisis.

Laryngitis and pharyngitis.—Fifty-eight cases were noted with reference to throat symptoms; 20 of this number complained of "sore throat." It was not practicable to make an extended examination of the throat under the circumstances, but by means of a tongue-depressor I was enabled to recognize more or less redness and tumefaction of the pharyngeal mucous membrane in 10 cases. It was judged by the huskiness and hoarseness of the voice and by the statements of the patients (some of whom were under treatment for their throats) that 4 of this number and 7 others were suffering with laryngitis. It did not seem to be severe in more than 5 cases, but in most of them the patients informed me that they had been unable to obtain much relief; 2 of the laryngeal cases, whom I had seen off and on for more than a year, retained the same husky, stridulous voice throughout this time. One case had well-marked tonsillitis and 2 complained of their throats in whom nothing of a definite nature could be made out. Some of the patients thought their throat trouble was due to violent attacks of coughing. Thirty-eight cases made no complaints of their throats when questioned and consequently were not examined. From these data it would appear that affections of the throat are quite frequent attendants of phthisis, but that the majority of them are not distressing nor of great importance.

Pulse, respiration and temperature.—The pulse was noted in 58 cases; the highest rate was 160 beats per minute; lowest, 68; average of all the cases, 110.77. The pulse-rate was observed to fall from 4 or 5 to 15 or 20 beats to the minute after the first excitement of the examination was over; hence, it was in all cases among the last points of which a record was made. The respirations were observed in 56 cases; the result was: highest rate per minute, 40; lowest, 17; average, 27.46. The temperature was taken in 48 cases; the highest noted was 103° F.; lowest, 96°; average of all the cases, 99.17°. This represents the sublingual temperature. The observations were made in most of these cases between 1:30 and 2:30 P.M. It should be stated that the pulse, respiration, and temperature recorded in the table were in each case the result of the first observation made on the patients. It was of course impossible to observe the diurnal variations in dispensary patients. As far as could be judged under the circumstances the temperature was a trustworthy guide to the progress of the disease; a high temperature meant usually rapid extension of the phthisical process. The pulse, respiration, and temperature did not always observe a *pari passu* rate. The pulse was usually most frequent in the early stages, the respirations in the later stages of the disease. Some of the advanced cases had very rapid breathing while the temperature was normal or even subnormal.

Complications.—Of the 59 tabulated cases, 32 were, so far as could be determined, free from complications. In some of the other cases the conditions indicated as complications might perhaps be better classified as symptoms. The cases with other diseases, or with symptoms severe enough to constitute complications, were as follows: Tertiary syphilis, 3; severe indigestion, 2; tapeworm, 2; and one each of the following, lumbago, exhausting diarrhœa, hemorrhoids, necrosis of the sixth (left) rib, extreme muscular debility, tonsillitis, nasal catarrh, laryngitis, hydrothorax and ascites, prolapsus uteri, "uterine disorder," constant facial neuralgia and toothache, abdominal neuralgia, chagres fever, intermittent fever (?)[1], mitral regurgitation with subacute pleurisy and extensive pulmonary emphysema. It will be seen that many of these troubles were trifling and unimportant; but we are struck with several points of interest. For example, the infrequency of cardiac disease as a complication. Each one of the 59 cases was carefully examined with reference to this point; in only one was an organic trouble found. Among several hundred cases of phthisis which I have seen at the physical diagnosis clinics of the Post-Graduate School, less than a dozen were complicated by valvular lesions of the heart. This would imply rather an antagonism than a causative relation between

[1] Pollock states that they occurred in twenty-six per cent. of cases analyzed by him (Flint's Practice of Medicine, Phila., 1881).

[1] The supposed periodical paroxysms of tertian intermittent fever in this case were afterward learned to be simply exacerbations of the fever attending the pulmonary trouble.

phthisis and organic diseases of the heart. Again, we are impressed with the infrequency of nasal catarrh in the list, only one patient having it at the time or mentioning it as an antecedent affection. This is greatly at variance with a widespread idea among the laity (and indeed among some professional men) that nasal catarrh is a frequent forerunner of consumption, and an important prodromic event. These complications were of course only such as could be elicited, or were manifest at dispensary clinics.

Lung Involved.—On physical examination the left lung was found to be involved in 22 cases, the right lung in 19 cases, and evidences of the disease were found in both lungs in 18 cases. It is highly probable that a necroscopic examination would have shown both lungs to be involved to some extent in a far greater number of cases, the fact being evident that slight phthisical or tubercular changes are often beyond the ken of a physical examination. When the disease extends over a long period it no doubt exemplifies quite fully the law of symmetry or parallelism. In the great majority of the cases in the early stages the disease was found to be limited to the apex. When no evidences of disease were found in this situation it was usually found that phthisis did not exist in the lungs. The disease seemed to observe a fairly uniform course, as will be seen by comparing the column containing "condition of lungs" with that containing "time of commencement." As a rule, in cases dating back for a few weeks or several months, evidences of catarrh were found at one or both apices. In cases with histories from six months to a year or two in duration, consolidation was usually present with more or less catarrh, while in cases extending back for several years, consolidation and cavities were the rule. There were several notable exceptions to this rule, however. Two of them will be cited.

Case 1.—Young man aged twenty-four, compositor by occupation. His disease commenced in April, 1885 (two months before examination), with a dry cough. Hæmoptysis, night-sweats, and great dyspnœa came on rapidly. When seen he was found to have a temperature of 103°, and extensive consolidation with unmistakable evidences of excavation were found in the left lung.[1]

Case 2.—Male, carpenter, aged twenty-eight. No heredity. Had articular rheumatism eight or nine years ago; commenced to cough seven years ago. Had more or less dyspnœa, and occasional hæmoptysis; expectoration was variable, night-sweats frequent; digestion was fair, although the appetite was generally poor. Patient was found to be low-spirited at the time of examination, and evidences of pharyngitis were discovered; he also had lumbago. The temperature was 102½°. On a careful physical examination no further evidences of phthisis than circumscribed catarrh of the left apex could be found. This was evidently a case of occasional irruptions with long remissions; he was probably suffering from a fresh outbreak at the time these observations were made. Several other patients who claimed to have been sick only a few weeks presented unmistakable evidences of phthisis.

It has not been my hope in the foregoing contribution to offer much that is new on the much-studied but never-hackneyed subject of pulmonary consumption. Some of the results arrived at are at variance with those of others, while many of them are simply in corroboration of past researches. In apology I would state, in the language of Professor Flint,[2] that "my object has been to study by means of numerical analyses my cases without reference to similar researches by others; and if the results of my analytical investigation are in conformity with those which have been already obtained this is certainly no disparagement of their correctness, nor does it impair their value as a contribution to our knowledge."

[1] This was a hereditary case. [2] Op. cit.

In conclusion I would offer my acknowledgments to Prof. Stephen Smith Burt, M.D., whose valuable clinical lectures have suggested many of the points in the foregoing investigation, and in whose departments at the Post-Graduate School and at the Out-door Department of Bellevue Hospital the cases were observed.

VOLVULUS OF THE SIGMOID FLEXURE RELIEVED BY OPERATION—DEATH FROM PNEUMONIA SIX DAYS LATER

By R. VAN SANTVOORD, M.D.,

NEW YORK.

H. T——, male, aged forty-five years, had been for thirteen years an inmate of the Randall's Island Pavilion for the insane. He was demented and unable to give any account of his own condition.

On June 30, 1885, he was observed to moan incessantly, to walk bent forward as if suffering from pain in the abdomen, and to go frequently to the water-closet.

On July 1st, being removed to the hospital, the abdomen was found to be slightly distended and quite tense. He made frequent attempts to have a passage from the bowels, but nothing came away. Abdomen somewhat tender.

On the third day of his illness abdominal distention was greater. Tenderness persisted. Bowels had not moved. Appetite failed.

On the fourth and fifth days of his illness, first castor-oil alone and afterward with croton-oil were given without effect. An injection brought away a small lump of hard fæces. Some hiccough occurred, but no vomiting.

July 7th, the eighth day of his illness, I saw him for the first time. The abdomen was greatly distended, very tense, and universally tympanitic on percussion. As the patient was said to be a stick eater, impaction of fæces was regarded as probable, and an injection was given with a stomach-tube and hydraulic pressure was attempted, at first in vain, owing apparently to the great distention of the abdomen. A moderately coarse aspirator needle was then introduced into the right lumbar region, that region being chosen because, owing to the tenesmus, the obstruction was supposed to be in the large intestine near the rectum, and the cæcum consequently was regarded as the most eligible portion of the gut to tap. A large amount of gas escaped. The rectal tube was re-introduced and pushed forward as the gut became distended with fluid. In all, twenty inches of tube and about a quart and a half of water were introduced. The abdomen was as tense as before. No fluid escaped on withdrawing the tube.

During the next two days other attempts were made to administer forced injections, but without result. A review of the case now led me to make a diagnosis of volvulus of the sigmoid flexure, based on the following grounds: The long duration (nine days) and absolute character of the obstruction, the absence of acute symptoms, such as vomiting and manifestation of great pain, and the large distention of the abdomen, pointed to obstruction of the large intestine. The large amount of gas drawn off from a single puncture pointed to the tapping of a distended colon rather than to a knuckle of small intestine. The tenesnus, the very great distention of the abdomen, and the absolute binding up of the bowels were regarded as pointing to volvulus of the sigmoid flexure, that particular portion of the gut being decided on because it is most frequently affected. Lastly, the retention of a large enema after passage of twenty inches of tube seemed best accounted for by supposing that the tube had passed an obstruction, which had recurred with its withdrawal. The large amount retained and the great tension of the abdomen rendered the classifying of this retention with that phenomenon, as ordinarily seen in the

[1] Read before the New York Pathological Society, January 21, 1886.

normal gut, hardly allowable. This last factor, together with the subacute course of the case, seemed to point to a not very tight twisting of the bowel.

The patient's pulse was rapid. He had no fever. His general condition was unfavorable. July 8th, ninth day of illness, being on duty at the time as visiting surgeon, as well as physician, I determined, in spite of unpromising conditions, to operate. The abdomen was shaved and washed with hot water and soap, followed by hot (1 to 200) carbolic water. The hands of the operator were carefully washed in the same solution before and at intervals during the operation. Clean towels wrung out of the same fluid were kept around the abdominal incision.[1] The patient being etherized, an incision four inches long was made in the median line just below the umbilicus. Under the peritoneum, before its incision, were observed bubbles of gas, which explained a crepitation which had been felt over the prominent portion of the abdomen since the puncture of the gut, two days before. On cutting through the peritoneum a small amount of slightly turbid, odorless fluid escaped. A congested, largely distended gut presented at the bottom of the wound. An aspirator needle was introduced obliquely into the presenting gut to reduce tension sufficiently to admit of safe exploration, and much gas was drawn off. On passing the hand into the abdomen the sigmoid flexure was found to have made a half twist on its axis, the lower and right portion of the loop having been carried forward and to the left, and the left and upper portion, which presented in the wound, backward and to the right. The distended flexure extended about two inches above the umbilicus, and one and a half inch to the right of the median line. Reduction was easily effected by drawing the lower limb forward and to the right with the left half hand and tucking the upper limb backward and to the left with the fingers of the other hand. It was now possible to follow the large intestine from the contracted rectum to the equally contracted descending colon, and to satisfy one's self that the obstruction was overcome. On the apex of the sigmoid flexure was observed an irregular, red, rough surface about two inches by four inches, found subsequently to be the muscular coat of the gut laid bare by rupture of the peritoneum.

The cæcum being greatly distended, the aspirator needle was thrust into it and much gas was withdrawn. On drawing out the needle a flow of gas continued. It was thought best not to attempt to suture the opening in the greatly distended gut, but to trust to the closing of the opening when the bowel emptied itself in the natural way. The peritoneum and external parts were closed separately with carbolized silk sutures. A copious flow of fluid fæces took place from the anus before the abdominal cavity was closed. The wound was dusted with iodoform, the sutures reinforced by rubber plaster, and a large pad of carbolized gauze and absorbent cotton was firmly bandaged over all. During the operation the pulse rose from 120 to 140. Temperature before operation, in rectum, 100°.

For three days the patient did fairly well. He had several loose passages a day. The abdomen became sunken. Two quarts of peptonized milk in twenty-four hours, whiskey, and morphia were given. On the fourth day the temperature went up and the patient began to lose strength. No abdominal symptoms manifested themselves, except that the abdomen again became distended in the epigastric region for two or three days before death. The wound looked healthy, no symptoms pointing to lung trouble were observed. It was not thought prudent to attempt physical examination of the posterior part of the chest. Death occurred from gradual exhaustion, six days after the operation, and fifteen after the first symptoms of obstruction were observed.

Autopsy, fourteen hours after death (unessential parts omitted).—The peritoneum was firmly closed at the site of the abdominal incision. The cutaneous incision was closed only for its lower inch, the rest of the wound gaping when the sutures were cut. There was no sign of inflammation, except a few drops of pus in the track of one of the cutaneous sutures.

The posterior half of the upper and middle lobes, and the posterior two-thirds of the lower lobe of the right lung were in a state of gray hepatization in spots apparently undergoing purulent softening. At the apex of the left lung was a cavity, the size of a pigeon's egg, filled partly with cretaceous, partly with thick, curdy matter. A few old cretaceous nodules were scattered through other parts of the lung. The posterior two-thirds of the lung was in a condition of red hepatization, with here and there lobules which were yellow and apparently approaching a cheesy condition. The portions of lung not hepatized were very œdematous.

One kidney presented a soft, white neoplasm, the size of a small marble, in the cortex, shown by the microscope to be an alveolar carcinoma. Kidneys otherwise normal.

Stomach.—Mucosa slightly thickened and injected.

Intestines.—The sigmoid flexure, cæcum, and transverse colon were much distended, the latter being about four inches in diameter. A very small amount of transparent fibrin, appearing like post-mortem coagulation of ascitic fluid, was seen here and there on the intestines. The intestines looked at points somewhat injected and dark from commencing putrefactive changes, but no peritonitis was present. Over the most prominent part of the sigmoid flexure was an irregular tear in the peritoneum, four by two inches. Similar, but smaller, tears existed over the cæcum and transverse colon. The points at which the cæcum had been punctured were represented by round, pigmented spots, perfectly closed.

Small intestine moderately distended. The mucosa of the small intestine was irregularly and slightly injected, and in its lower part thickened. The mucosa of the largely distended cæcum and transverse colon was intensely injected, and appeared to be slightly ulcerated on its surface. The splenic flexure and descending colon, which were contracted, showed an irregular strip of deep and old ulceration, extending longitudinally, above one inch in width, and containing long strips of mucosa, with long and narrow ulcerations on either side. About four inches above the commencement of the sigmoid flexure, the gut was still narrower, and an irregular band of red, slightly elevated tissue presented, extending for about four inches, diminishing and disappearing rather gradually at either end.[1] The mucosa of the sigmoid flexure was thick, œdematous, and injected. Its veins were distended, and tortuous.

The meso-colon of the sigmoid flexure was somewhat thickened, but presented no other abnormality.

Retro-peritoneal glands not enlarged.

In my remarks upon this case, I follow in the main the able monograph of Frederick Treves on intestinal obstruction. According to this authority, volvulus of the sigmoid flexure about its mesenteric axis constitutes about two-thirds of all cases of volvulus. The anatomical condition necessary for its production is said to be a long loop, with narrowing of the meso-colon at its parietal attachment. This arrangement of the parts he states may be congenital, but, as volvulus of the sigmoid flexure is "extremely rare in the young," such a circumstance must be uncommon. Peritoneal adhesions, cicatricial contractions, and above all, the dragging down of the meso-colon by flatus and fecal accumulations in the sigmoid flexure, are the common predisposing causes. The mechanism in my case does not apparently fall exactly under this heading, because there was no appreciable deformity of the meso-colon. I believe that the following is the explanation in this particular case. The descending colon was very much contracted down to its junction

[1] The instruments were kept in 1 to 2000 carbolic solution. Two silk ligatures used were soaked in the same.

[1] Microscopic examination showed that this thickening was entirely inflammatory.

with the sigmoid flexure, the transition at that point from a rigid to a very distensible portion of gut being marked. It is conceivable that at the time of the occurrence of the volvulus the sigmoid flexure was distended by flatus, twisted upon itself during its vermicular contraction, and that the lower limb of the flexure became caught and retained between the shoulder formed by the abrupt transition from the stenosed to the dilated gut immediately below and the anterior abdominal wall. I have illustrated my idea on the little cadaver here presented. The ulceration and inflammatory changes in the bowel were probably due to the constipation common in the insane, the irritant effect of the bowel contents being increased by the foreign bodies which he was alleged to swallow.

On analyzing the symptoms presented during life, the combination of tenesmus, absolute constipation, and rapid distention of the abdomen were highly suggestive of the condition found. Marked tenesmus points almost invariably to a lesion of the large intestine, though Treves records two cases of volvulus of the lower part of the ileum accompanied by severe tenesmus. It occurs, also, to some extent in intussusception of the small intestine. It was a marked feature in fifteen per cent. of cases of volvulus of the colon, and in fifty-five per cent. of cases of acute and subacute intussusception, the latter usually involving the colon. In these latter cases absolute constipation is "extremely rare" (Treves). Moreover, distention of the abdomen is rare in these cases, also. Whether or not existing tenesmus depends upon stricture or other lesion of the large intestine in a case of intestinal obstruction can best be determined by the previous history, a source of information which my patient's mental condition rendered unavailable. In many cases of volvulus early development of peritonitis, commencing in the twisted meso-colon, causes a local tenderness which is of importance in diagnosis. In my case the patient's mental state rendered it impossible to form any accurate idea of his subjective symptoms. As there was no peritonitis, there probably was no local tenderness. The absence of vomiting and of the other symptoms of great acuteness of attack, such as marked shock and suppression of urine, pointed in a general way to obstruction of the large intestine. Treves has pointed out, however, that these symptoms depend rather "upon the nature of the occlusion than upon its situation." It is the very lesion which I am now discussing which "may present symptoms as violent and as rapidly developed as any met with in acute strangulation of the small intestine."

The fact that a very large amount of gas was drawn off from a single puncture at the site of the ascending colon seemed to prove that the distended colon had been punctured and not a knuckle of small intestine. This is a diagnostic point accidentally hit upon, to which I have seen no reference, and which seems to be of value. Whether or not tapping of the gut is justifiable, except as a step preliminary to operation, may be an open question. The general reduction of abdominal tension by aspiration or puncture has been recognized as of value in facilitating diagnosis. A striking exception to the rule in my case was the passage of the tube past the obstruction, twenty inches into the sigmoid flexure, and the retention of a quart and a half of water. As a rule, this is not possible, and enemata only as large as can be accommodated by the rectum can be injected. The deep introduction and injection were possible only after reduction of the tension of the abdomen by the drawing off of gas. The passage of a tube past an obstruction and the retention of a large enema is a source of fallacy to which attention has been called. It has been noted, for instance, in intestinal stricture, in which a mass of hardened fæces acts the part of a ball-valve, preventing the passing downward of fluid. This occurrence in my case I interpreted as indicative of a comparatively slight twist in the gut, and my conclusion proved to be correct.

The use of the long tube as a means of diagnosing the site of an obstruction is one which is recognized as being attended by sources of error. In my case it was, on the occasion above cited, actually pushed through one place of obstruction. In others, it doubles back upon itself. It is claimed by some observers that it is possible to reach even as far as the transverse colon or beyond with a tube introduced into the rectum. Treves states that he has "good reasons for doubting if these rectal sounds ever go beyond the sigmoid flexure."

I desire in this connection to call attention to the fact that a sound, in going round the curves of a normal sigmoid flexure, is of necessity guided by the inner concave surface of the gut, rendered resistant by distention, and must be equal in length to the gut traversed. The normally developed large intestine, from the anus to the splenic flexure, may be roughly stated as being from one-half to two-thirds the length of the individual. To reach the splenic flexure in an adult, therefore, would require a tube at least two and a half feet, and oftener three feet or more in length. In experimenting on the bodies of infants, on one occasion I succeeded in passing a catheter into the transverse colon after the abdomen was opened. How often, if at all, this can be done in the living, unopened subject, I cannot say. It, at least, can be positively affirmed that the passage of a sound in a straight, or approximately straight, direction in a person with a normally developed sigmoid flexure, from the anus to the umbilical region, or even as high as the diaphragm, proves nothing except that the sigmoid flexure is very distensible and movable, or that the operator has perforated the gut, a thing which is not very difficult to do, at least in a dead baby. With regard to the treatment, the administration of cathartics in the early stage of the case, when the patient was supposed to be suffering from ordinary constipation, was of course wrong. After the true nature of the case was suspected they were of course discontinued. The error of the House Physician was excusable, owing to the frequency of obstinate constipation in the insane, their insensitiveness to grave affections, and, in demented cases, their inability to describe their ailments.

The result of the intestinal puncture, in admitting gas to the peritoneal cavity, was an illustration of the danger of this procedure, though it did not have any obviously bad effect on the patient's condition. This may have been due to the fact that the gas was not absorbed. At least quite a number of bubbles were still present under the peritoneum at the operation, two days after the puncture. The great tension of the abdomen probably accounts for this non-absorption, the relief caused by the withdrawal of gas being quickly offset by the injection of water. This episode suggests the possibility that the distention of the intestines in peritonitis may be conservative, by preventing or diminishing absorption of septic matter. In some cases of volvulus of the sigmoid flexure, however, the distention has been so great that death resulted apparently from pressure upon the thoracic viscus.

Laparotomy for volvulus has proved very unsatisfactory. The cases are usually very acute. The enormously distended coil of gut is difficult to handle. Even when reduction is effected the predisposing cause remains and recurrence is probable. In my case the coil of gut was comparatively small. Reduction, or even safe exploration of the abdomen, would have been impossible without preliminary aspiration of the intestine. It is to be remarked that the introduction of an aspirator needle obliquely through a chosen portion of exposed gut is materially safer than the haphazard thrusting of a needle through the walls of an unopened abdomen.

To prevent recurrence it has been proposed by Treves to fix the apex of the coil in the abdominal wound and make an artifical anus.[1]

In my own case it seems reasonable to suppose that an earlier operation would have resulted differently.

[1] Medical Record, vol. xxvi., p. 171.

Careful regulation of the bowels would perhaps have been more successful in preventing recurrence than in the more common cases of narrow pedicle, long loop, and more extensive twisting of the intestine.

Clinical Department.

AN INSTANCE OF REMARKABLE FECUNDITY.

Dr. Joseph N. Steedy, of Cambridge City, Ind., reports the following rare case: On May 3, 1884, he delivered Mrs. S——, aged sixteen, of a healthy female child, weighing nine pounds. On February 2, 1886, he delivered the same woman, then eighteen years of age, of three female children. All were born alive and weighed, respectively, four and three-fourths, four and one-fourth, and five and a half pounds. The first presented by the vertex, the second by the face, and the third by the foot; each in a separate sac. There was one large placenta, the three cords being attached to the margin at about equal distance from each other. There was about thirty minutes' interval between each birth. These children were born under the most unfavorable circumstances, and with a temperature outdoors of from 10° to 18° below zero. They were all alive at the time of Dr. Steedy's report, and seemed as strong and vigorous as children of their weight usually are when born singly.

ANTIPYRETIC TREATMENT.

Dr. M. A. Veeder, of Lyons, N. Y., sends us the following: The use of certain drugs for the purpose of reducing the temperature is very liable to become a mere matter of routine. The ease and certainty with which fever is detected by means of the clinical thermometer leads to the habitual use of this instrument, with the effect of concentrating the attention upon changes of temperature to the neglect of other symptoms. The obvious consequence of this tendency is an undue reliance upon fever mixtures of one sort or another. In regions where this therapeutic fashion holds full sway but few patients escape being dosed with quinine, aconite, the salicylates, antipyrin, or some other wonderful antiphlogistic. Unquestionably such drugs have their proper uses, but they should not, therefore, be employed haphazard in every case of elevation of temperature. In fact, their routine use does harm by preventing the adoption of measures having real efficiency. In typhoid fever, for instance, it should not be forgotten that healing the ulcerated bowel moderates the fever most effectually. It has been the fortune of the writer to see an extremely severe case of typhoid recover without the use of any of the ordinary antipyretics, the high temperature as well as the other symptoms yielding under treatment directed almost entirely to remedying the condition of the bowel. Thorough digestion of the nourishment given, and the use of turpentine, bismuth, and opium, in accordance with their well-known effects, were the means employed. The principle involved in this method of treatment is to attend first to the primary lesions of the disease rather than to its symptoms. Fever will cease if the disorder upon which it depends has been remedied. Thus fever dependent upon indigestion can be relieved, not by aconite or quinine, but by clearing out the bowels. A stimulating expectorant like carbonate of ammonia, liquefying and removing foul accumulations, will often have a more decided effect upon the temperature than any of the regular antipyretics. In case of sore throat with bad breath, chlorine water, attacking the disorder in its very seat, may relieve all the symptoms, feverishness included. Certain malarial fevers may have their power broken by methods that do not involve the swallowing of any drugs whatever; only clean out the filthy cellar or the nasty drain, or trap the sewer on the premises, and fever takes its departure like a whipped cur. Improper splints or bandages may cause feverishness after surgical operations. In such cases, instead of dosing with quinine, smooth out the wrinkles and put the wounded part in as comfortable a condition as possible, and the patient becomes as serene as a morning in May. Puerperal fever not unfrequently disappears, as if by magic, when the uterus has simply been freed from malodorous materials, and thoroughly disinfected. In dealing with wounds and sores generally, absolute cleanliness is the best antipyretic. In fact, the whole subject of antiseptic treatment, which looms up so largely in these days, may properly be regarded as but a phase of the subject of antipyretic treatment. As a result of modern researches into the nature of disease-germs and wound-infection it is evident that physicians are fast becoming better able to deal with the causes as well as the symptoms of disease. It is safe to say that the time is approaching when Medicus will no longer thrust a fever thermometer beneath his hapless patient's tongue, and then with an air of vast scientific superiority prescribe a fever mixture hap-hazard.

DISLOCATIONS OF THE SHOULDER-JOINT.

Dr. Thomas H. Manley, of this city, writes that his experience during the past year with luxations of the shoulder has led him to regard the accident as a much more serious one than is generally supposed. It is impossible to tell from inspection, immediately after dislocation has occurred, how easy or how difficult its reduction will be; and after repeated attempts at reposition have been made without success, another effort, perhaps by another surgeon, may be followed by the desired result. He says that of 10 cases seen by him in the past year, 8 were subglenoid, and were easily reduced, while 2, which were subcoracoid, were absolutely irreducible. In the successful cases ether was used only once, its administration being required on account of the severe pain. In one of the irreducible cases, occurring in an epileptic, the effect of ether was to cause a tetanic rigidity of the muscles, which, at times, became so general and so marked as to interfere with respiration. The writer believes that ether is seldom required, despite the generally accepted opinion to the contrary. Its principal value is to relieve pain, but it is questionable whether the relaxed state of the muscles which it induces is of any real value to the surgeon in the majority of cases. Dr. Manley sums up with the following conclusions: 1. The surgeon should not attempt the reduction of a dislocated shoulder without the aid of an experienced assistant. 2. Without great caution in manipulation and care not to use violence, he may very seriously injure the joint by lacerating the tissues, or fracturing the bone. 3. With the best directed efforts some dislocations of the shoulder cannot be reduced.

A FAILURE WITH COCAINE.

Dr. Charles B. Kelsey, of this city, writes: The successes of cocaine are so many, and the failures so few, that each of the latter is of interest. My own was in a strong, healthy man, aged thirty-one, suffering from an ulcer within the rectum. Desiring to dilate the sphincter, and make an application to the diseased spot, I injected forty minims of a four per cent. solution, ten minims each in four different spots around the anus. There being no appreciable effect after fifteen minutes, I again injected fifteen minims of the same solution at two other points—fifty-five minims in all. Ten minutes after the second injections I dilated the sphincter, and although I cannot be sure that the cocaine did not lessen the pain, the effect was not at all such as I desired. The constitutional effects, however, were well marked. One week later I repeated the same operation on the same patient, beginning with thirty minims of a four per

cent. solution, and following it in ten minutes with fifteen minims more. The injections were made at four points in the circumference, the needle being entered just within the anus. The sensibility was tested every two minutes after the first injection; the pain of the punctures for the second injections was fully as great as for the first, and after twenty five minutes I operated without the least appreciable benefit from the cocaine. The article was good, as is proved by my having used it two days before with perfect success; and the failure was not due to the method of application, because I have applied it in the same way to many other cases of rectal operations with perfectly satisfactory results.

Progress of Medical Science.

Blindness Due to Simple Anæmia.—An interesting example of the possibility of simple anæmia producing complete blindness has lately been seen by Professors Litten and Hirschberg in Berlin. The patient was a girl, aged fifteen, who for some short time previously had noticed that her sight was becoming dim, and who for the last two days had been quite blind. She was well formed and stout, but pale and badly nourished; the menses were regular and abundant. She complained of spasmodic pains in the stomach, and this probably was the cause of the malnutrition. The internal organs were healthy; the heart-sounds clear; there was a loud hum in the jugular veins; pupils equal, dilated, and insensitive; sensorium normal; amaurosis complete; papillæ swollen; optic nerves slightly reddened and dull, the edges much swollen; veins distended and contorted; urine normal; blood thin and bright, presenting the well-known characters of anæmic blood—mycrocytes, club-, pear-, and pessary-shaped blood-corpuscles; white corpuscles slightly increased. Anæmia was evidently the real cause of the amaurosis. The girl was put to bed and well fed, and syrup of iodide of iron prescribed. The stomach trouble and appetite soon improved, and in a month's time the condition of the blood and the ophthalmoscopic appearances had become normal. It is worthy of remark here that the appearances were not such as are found in pernicious anæmia—complete pallor of the papillæ, bright redness of the veins, and streaks of blood. The prognosis therefore was good, and was fully justified by the result.—*The Lancet.*

False Tabes.—Under the name of "tabes dorsalis illusoria," Dr. Kovalevski reports a case of hysteria in which the symptoms were very similar to those of locomotor ataxia. The patient was a man, thirty-seven years of age, of previous good health, who had experienced considerable mental anxiety. He had pain in the back, lancinating pains in the limbs, an uncertain walk, especially with closed eyes and in the dark, weakness and heavy feeling in the legs, a feeling of constriction around the body, tightness of the chest, vertigo, constipation, and retention of urine. The patient was sleepless and exhibited suicidal tendencies. Objective examination revealed nothing abnormal. A course of treatment by excessive physical exercise, general faradization, good nourishment, and douching brought about a complete cure in twenty-three days.—*Centralblatt für klinische Medicin*, January 2, 1886.

Pseudarthrosis.—M. Berger presented to the Surgical Society of Paris a specimen of pseudarthrosis of the leg taken from the body of a man fifty-seven years old. The condition had existed exactly fifty years, and the abnormal articulation was remarkable for its perfection. The upper fragments of the tibia and fibula were cup-shaped and received the ends of the lower fragments. There were no cartilages, but the extremities of the bones were eburnated, and were surrounded by exostoses similar to those seen in arthritis deformans. A capsule formed of thickened periosteum covered the ends of the broken fragments, and held them together. The tendons ran across this false joint in true synovial sheaths. There was no apparent atrophy of the neighboring muscles, but the foot on this side was only three-fourths of the size of the other, the bones of the leg were shortened, the patella was small, the corresponding half of the pelvis was less developed, and there was a lateral spinal curvature, the body being inclined to the affected side. M. Trélat, in commenting on the case, was inclined to the opinion that the pseudarthrosis and atrophy were the result of a nervous lesion, as, for example, atrophic infantile paralysis; for there was considerable bony atrophy, and the fracture had taken place at an early age, when pseudarthrosis very rarely occurs.—*La France Médicale*, January 16, 1886.

The Abdominal Bandage after Labor.—Professor Czerny writes in the *Centralblatt für Chirurgie*, of January 16, 1886, that he has been struck with the fine figures of English ladies, even after they had gone through numerous pregnancies. He attributes this preservation of form to the habit of English accoucheurs of applying an abdominal bandage immediately upon the completion of labor, and urges the adoption of the practice by German physicians and midwives. It is interesting to learn that this idea has reached Heidelberg, and there is reason to hope that the Teutonic matron of the next century will be happy in the possession of a smooth and finely rounded abdomen.

Pessaries.—Dr. Leopold Meyer writes upon this subject in the *Hospitals-Tidende*, and recommends a pessary formed of copper wire covered with a soft rubber tube. The rubber is to be painted over with iodoform-collodion (1 to 15) and may then be retained for three or four months in the vagina without acquiring any odor.

Late Hereditary Syphilis.—Under this name are included the manifestations of the so-called tertiary period of syphilis which make their appearance at a considerable period after birth, usually about puberty, without any prior symptoms of the disease. Zeissl has collected the records of over a hundred such cases and adds a number seen by himself. The disease affects chiefly the osseous tissues, more especially the bones of the nose, and also the nervous structures and the organs of special sense. The author asserts that Hutchinson's triad (deformity of the permanent incisor teeth, parenchymatous keratitis, and diseases of the auditory apparatus) points only to a probability of the existence of hereditary syphilis; these symptoms may be present without syphilis, and may be absent when the disease is actually present.—*Centralblatt für klinische Medicin*, January 16, 1886.

Turpentine in the Treatment of Fistulæ.—Dr. S. Cecchini has employed injections of oil of turpentine in the treatment of fistulæ and indolent sinuses, and reports in detail a number of successful cases. The turpentine acts both as a stimulant to the granulations and as an antiseptic. In seven cases of anal fistulæ he obtained a perfect cure in five. The injections were made by means of blunt pointed cannulæ, and were repeated at intervals of three or more days. The pain caused was only moderate, but when necessary, the turpentine was diluted with almond or olive oil. In four cases of caries of the temporal bone in children a complete cure was obtained in from two to three months. The fistulæ were washed out with a solution of boracic acid before each injection. A like favorable result was obtained in eight cases of dental fistulæ complicated with more or less extensive caries of the alveolar process and jaw. One case of fistula of Steno's duct was cured by eight injections in thirty days. In a number of other cases of indolent fistulæ not due to caries, a favorable result was obtained in from ten days to a month. Finally, two dissection-wounds which the author had acquired were healed by turpentine in four and nine days respectively. —*Centralblatt für Chirurgie*, January 2, 1886.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 20, 1886.

THE LATE DR. AUSTIN FLINT.

DR. AUSTIN FLINT had long been rightfully regarded as the best representative of the best type of American physician. In personal character, in scientific attainments, in practical experience, and in the art of dealing successfully with his patients and his fellow-men he leaves behind no equal. Dr. Flint had a presence which inspired confidence, and a genial manner which won friendship and kindly feelings from every one with whom he came in contact. Beneath his geniality, however, was an indomitable will and strength of purpose which he could exhibit when occasion called. He had that fortunate combination of elements in his character which enabled him to achieve the completest success attainable to medical men without awakening envy or creating enemies. Few men have been so justly eminent and yet so widely beloved and admired.

Dr. Flint contributed largely both to medical literature and medical science. His works and writings were an immense help to American medicine. No other single American author has done so much to give our profession a standing before the world. At various times Professor of the Practice of Medicine in six different medical colleges, his experience and studies were naturally kept broad, while at the same time his knowledge was made exact. This was shown in his systematic writings, which always showed painstaking research, a judicial mind, and were free from any taint of personal bias or useless speculation. We doubt if Dr. Flint ever had a genuine "hobby;" if so he kept it from his writings.

Dr. Flint's contributions to clinical medicine were numerous, and many of them were positive advances in medicine. Perhaps his name will be longest associated with the study of physical diagnosis. Among the earliest to teach the utility of this art, he added greatly to our knowledge of it, particularly as regards the nature of the sounds in pulmonary phthisis and in heart disease.

The honors which Dr. Flint received, especially during the last years of his life, were all that medicine can bestow upon its most favored followers. Though an old man, age had not in the least dimmed his faculties or abated his activity, and his death seemed as premature as it was unwelcome and sad. American physicians can never cease to honor his memory, and we trust will never fail to emulate his virtues. If our art is not the greatest, it can at least be proud that it produces such men as the late Austin Flint.

THE RHYTHM OF FEVER.

A CORRESPONDENT sends us an interesting and very clearly presented *résumé* of the arguments in favor of the nervous origin of fever. He correctly states that the view that fever is proximately a neurosis is now established on almost impregnable ground. The opinions of Liebermeister, and the experiments of Wood, to which we may add those of Eulenberg and Landois, of Sachs, Hitzig, and Bechteren, are referred to and quoted.

But beyond this our correspondent offers a suggestion of his own. He says: "The phenomena of fever are better explained upon the supposition of the disturbance of a heat-centre by applying one of the corollaries of the persistence of force, as given in the principles of evolution, viz., that of the rhythm of motion. Mr. Spencer has shown us that, as a deduction from the persistence of force, there must follow the fact that all matter is in a state of vibration which is rhythmic in character. Periodicity, rise and fall, maxima and minima, this is the law of all matter whether molecular or ponderable. Applying, then, the rhythm of matter to the hypothesis of a thermal centre, we see that the daily oscillations of that centre, the rhythm, rise and fall, may correspond to the diurnal rise and fall of temperature which we know takes place in the body in health. Suppose this centre to be disturbed by shock of certain kinds, then the molecules in their vibrations will take a wider range of divergence, and vibrating across the median line of normal temperature will, as they swing to one extreme, unduly stimulate the inhibitory power of its conducting nerves, and depress the heat-production and heat-dissipation to so low an ebb that a degree of cold, perhaps a chill, results. Then as the oscillation carries it across the median line of normal temperature to the limit of its opposite range the undue stimulation will be succeeded by its opposite of partial paralysis of its inhibitory power, with the resultant of over-production of heat. Again, as the extreme of paralysis is reached and the oscillation tends to resume its equilibrium, at that point as it is reached the heat-production and heat-dissipation again balance each other, and the normal temperature is the result. This moving equilibrium, as Spencer denominates it, may be maintained here, or the shock may have been sufficient to cause successive vibration across the median line of normal temperature with their resulting effects of chill, fever, and period of intermission, or in other words, all of the phenomena of intermittent fever, the rhythmic rise and fall of which would correspond closely with the rhythmic vibrations of the nerve-centre, which are a necessity as a corollary of the persistence of force. Or suppose the primary shock to have been sufficient to displace the oscillations entirely to one side of the median line of normal temperature. In jelly-like masses of matter, we may see such vibration entirely to one side of the perpendicular line of gravity.

"In such a case there would ensue a continuous paralysis of the inhibitory forces, resulting in a steady overproduction of heat, but varying daily as the oscillations occurring in their range outside o the median line approach first to the normal and then swerving outward to the range of greatest limit. Thus may the daily rhythm go on for weeks, in conjunction with its outer rhythmic expression, in enteric fever, until its tendency to seek its normal

equilibrium being greater than the primary shock the oscillations finally touch the normal point and rest there, or perhaps swing outward again for a few times, as we sometimes see in the closing days of a fever, to ultimately resume their wonted position of a moving equilibrium across the line of normal temperature.

"These may seem but idle speculations, but with the exception of the assumption that the rhythm of fever corresponds with the rhythm of the molecular mass in the heat-centre there is nothing speculative about it.

"It would account also for the self-limiting character of fever, since the tendency of all bodies in motion is to rest; the original shock to the heat-centre having spent itself the tendency of that centre would be to a state of rest and thus to a limitation of the fever. Whether the original shock to the nervous centre be due, as Liebermeister surmises, to the 'reflex irritation of cold,' or whether it is due to the material impact of a germ is a matter of no moment as regards the rhythm of fever."

We shall dismiss our correspondent's suggestive communication with the single comment that he appears to forget that in a chill both the temperature of the body and the heat production are increased, though heat excretion is temporarily lessened.

RELATIONS OF STATE AND LOCAL HEALTH AUTHORITIES.

In proportion as the population of a country grows more dense the struggle for health becomes more difficult, while at the same time it is the more necessary to the individual, since existence is harder and sickness takes away the ability to earn. The establishment of certain laws and regulations designed to improve the sanitary conditions of localities thus becomes imperative. That the laws at present in force are not perfect few will be disposed to deny, but they must answer until new regulations, better adapted to the purpose, can be formulated and put into execution.

Dr. Maurice Perkins, of Schenectady, sends us an interesting article, embodying some suggestions on this point, which we reproduce in brief. He does not favor the idea of referring matters of this sort to commissions, but thinks they should be subjects of political interest, to be discussed freely by all voters. It would be possible, he says, for some State officer, as the State Engineer, to have a health department under his control, and for its success and usefulness the people could hold him responsible at the polls. "But it is to the local health officer," Dr. Perkins writes, "that we should look for the best results, and everythin snould be done to magnify his importance, and care should be taken that he is fitted for his work. I would have him appointed directly by the official head of the city or town, and selected from a list of candidates who have passed a proper examination. I would have the state officer a court of appeal to settle differences between health and other local authorities as to powers, etc., and would have him in constant communication with local officers, demanding from them news of epidemics and such matters, and transmitting the reports to all others, that they may be informed as to possible danger. He should offer prizes for the best yearly reports from health officers, and should encourage the publication of original papers on hygienic subjects." The writer thinks that the State should not interfere in the matter of sewerage or the water-supply of towns, but should leave such matters to the consideration of the voters in the locality interested, and he also disapproves of the sending of experts, either medical or sanitary, from one place to another, believing that, were local authorities relied upon to a greater extent, they would soon manifest their competency for the work imposed upon them. In short, Dr. Perkins believes thoroughly in home rule, as far as sanitary matters are concerned, and he would restrict the power of the State as far as possible consistent with order and the public safety.

A FOOLISH SOCIETY.

The St. Louis Medical Society has passed a resolution positively prohibiting the publication of its transactions, or any part or synopsis thereof, in any medical journal, and directing that "no member of or visitor to the Society shall transcribe its proceedings, or any part thereof, for publication, nor publish an epitomization or synopsis of the same."

The object of this act was to prevent the publication of partial and mutilated reports.

The Society is evidently neither wise nor experienced. In time it will learn that seventy-five per cent. of society discussion is rubbish, and that medical journals cannot publish them in full and live. No society can long force upon the public, by "Transactions" or "organs," material not worth publishing.

A NEW FORM OF LUNG DISEASE.

In 1877, Bollinger showed that the disease of cattle ordinarily known as "swell-head" or jaw-sarcoma was due to a fungus, and he called the disease actinomycosis. To Ponfick belongs the credit of having first detected this disease in man.

Since attention was called to it a number of other cases have been reported. Dr. P. B. Conti recently published the history of a case of actinomycosis occurring primarily in the human lungs. He has also collected sixteen other cases, and from a study of them has been able to give a tolerably good picture of primary broncho-pulmonary actinomycosis, or, as it may be called, actinomycotic phthisis. Although nearly all the cases so far observed have been found in Germany, it is not at all improbable that the affection occurs in this country, since the researches of Dr. W. T. Belfield have shown the prevalence of the actinomyces in American cattle. It is all the more important that physicians should have their attention drawn to it, since the disease closely resembles in its general course acute phthisis, while at the same time presenting some very pathognomonic signs to those who are on the lookout for them.

The disease begins insidiously, the actinomyces reaching the deeper bronchi by inspiration and lodging there. A local irritation is caused, and the patient has the signs of a bronchitis. This is very soon followed by a circumscribed broncho-pneumonia. The sputa, if examined in this stage, would reveal the real trouble, but it could be detected in no other way. The disease extending, causes peri-bronchitis and interstitial pneumonia, and then the pleura becomes involved. There is

sometimes a circumscribed adhesive pleuritis, at other times a sero-fibrinous exudation or a purulent pleurisy. Some cases apparently begin in the pleura, but it is probable that even here there was originally a pulmonary invasion which speedily extended to the pleura. In the last stage of the disease the thoracic wall itself is invaded, a peri-pleuritis taking place. Indolent, œdematous tumors appear, which are often the first thing that calls attention to the true nature of the trouble. These tumors finally suppurate and may open and discharge externally.

The disease runs a course lasting about ten months and is, we believe, always fatal. Wasting is very slow. The course is generally apyretic, and the chest finally becomes distorted. Only a microscopic examination of the sputa can positively differentiate the disease from cancer.

It is to be hoped that American physicians living in the West, where the opportunities for observing this disease occur, will report any cases that come under their observation. While pulmonary actinomycosis can probably not be cured, it can at least be prevented.

The complications which may arise are those of metastasis, the actinomyces getting into the blood-vessels and giving rise to embolisms. The general symptoms are much like those of a catarrhal phthisis, or perhaps still more like those of pulmonary cancer. In the later stages the disease seems to resemble septicæmia.

Characteristic features of it are scanty sputa, disagreeable in odor, having a currant-jelly like appearance, containing no blood, but showing under the microscope the characteristic appearance of the actinomyces.

HOSPITAL MANAGERS AND MEDICAL BOARDS.

In the relations between the governing boards of hospitals and the medical staff there often arise serious difficulties, ending but too uniformly in the humiliation of the latter. With hardly an exception it is the medical men who are defeated and made to suffer when any contest arises. The managers control the revenues, the doctors contribute their services, and are often made to feel that they are in fact only a higher grade of employee.

Occasionally, however, the physicians make a good fight, and even a successful one, against the unjust usurpation of their privileges by the governing boards. Such a case has occurred in Halifax, N. S., and the particulars of it are instructive. The Medical Staff of the Provincial and City Hospital had for seven years been in the habit of appointing the House Surgeon after a careful competitive examination, awarding the appointment to the candidate who took the highest mark. Last spring the usual examination was held, and the appointment of Dr. Goodwin was recommended to the Board of Commissioners. These latter gentlemen, instead of confirming him, appointed a Dr. Hawkins, who had stood much lower in his examination record, and who was not, therefore, recommended by the Board. The Medical Board protested and asked for explanations, but being treated rather curtly, after negotiating for six days, they all resigned. In this act they had the uniform support of the profession of the city at first. Sad to relate, however, later in the day some men finally consented to take the vacant places.

The old Medical Board has, however, wisely continued its struggle, and is, we are informed, securing the support of the profession throughout the province. A petition has been drawn up, addressed to the provincial Government, asking that the matter be investigated, and that the authority of the Medical Board be given a definite legal status. This petition is being extensively signed by the physicians of Nova Scotia, and we trust that they will unite in supporting the Board in its struggle. While the question at stake is not a great one, it involves a principle, and if the physicians succeed in establishing their rightful demands, it will be a helpful precedent in future controversies.

THE "DRY TREATMENT" FOR UTERINE DISORDERS.

In a paper read before the St. Louis Obstetrical and Gynecological Society, Dr. George J. Engelmann brings forward what he terms a new departure in uterine therapeutics. Preliminary to a description of his own methods, Dr. Engelmann gives an interesting sketch, showing the national peculiarities of gynecologists, so far as topical therapeutics is concerned. "In Germany," he says, for instance, "at one time the washing of cervix and vagina with strong solutions was an almost universal practice; in many clinics it was customary, whether other treatment was applied or not, to wash cervix and vagina with strong solutions of sulphate of copper, or carbolic acid, through the Ferguson speculum. In France—I am only speaking of methods which are not used here—they use the cautery, and medicated supports to the uterus; the thermo-cautery also is a specialty in French gynecology; a common usage is to apply a remedy in a small semicircular bag made of muslin or mosquito-bar, which at the same time serves as a support for the uterus. This country is peculiar in its use of nitrate of silver and iodine, though in England it is used in a similar way, but by no means as freely and as commonly as here."

Dr. Engelmann's new departure consists essentially in the use of medicated absorbent cottons, with or without the addition of a powder-blower, or gelatin pencils. The medicated tampons have the advantage, we are told, of giving support to the uterus, of acting continuously and evenly, and of being cleanly. The tampons may also be made of jute, and perhaps the best combination is a medicated jute tampon covered with a layer of the softer cotton. The powders used are those of alum, bismuth, tannin, salicylic acid, iodoform, and zinc. Next after these in value are the gelatin or iodoform pencils. The cotton or jute used is medicated with iron, boracic acid, alum, tannin, iodine and other substances.

By the use of the powders or pencils and tampons, in endocervicitis, erosions, and other chronic uterine troubles the profuse discharge is often checked very promptly, and a healing process set in action. Dr. Engelmann does not recommend the glycerine tampons which are considerably used in this city. His "new treatment," though a good one, is not, we venture to say, very new, something very much like it, *i.e.*, the use of powder and cotton tampons, was, we believe, at one time quite the routine practice in Vienna. In this city also cotton tampons medicated with alum and other powders have been used for six or more years.

THE PROPHYLAXIS OF GONORRHŒA.

PREVENTIVE medicine is certainly attaining a catholicity of scope and an unexpected multiplicity of ramifications which ought to gratify its supporters. Dr. Haussmann, of Berlin, applying the same mental machinery of analogous reasoning used by Bishop Butler of immortal memory, inferred that because nitrate of silver prevented gonorrhœal ophthalmia in infants born of women suffering from gonorrhœa, it would also prevent gonorrhœa in persons no longer infants who exposed their sexual organs to infectious influence. By what means he persuaded anyone to an experiment we do not know, but European physicians have a strong influence over their patients, and at any rate, he found that an injection of a two per cent. solution of nitrate of silver into the urethra, at most a quarter of an hour after cohabitation with an infected woman, proved a very effectual means of preventing infection.

Dr. Haussmann speaks only of the male, thus giving a mild suggestion of the Teutonic idea, that woman is a useful breeding and housekeeping animal—but not much more.

A French sanitarian in the gonorrhœal field, however, comes in opportunely, and in response to his natural gallant instincts suggests a remedy for the woman as well as the man. He advises that prostitutes should have on hand a supply of a solution of bichloride of mercury, 1 to 500, this to be used by themselves and their male visitors! Such applications of science are repulsive and degrading, yet we can hardly say that they are wrong. Sexual crime will not be lessened because it involves the danger of disease, but because it causes moral and social injury.

This prying of preventive medicine into brothels imparts to it something of nastiness, but it may be useful for all that.

News of the Week.

THE PHOTOGRAPHS OF CIGARETTE MAKERS.—We have been informed that the photographs to which reference was made in our last issue do not represent, as we supposed, the operatives in the cigarette factories of Richmond, but merely models who pose for various industries. The pictures which are considered objectionable have been withdrawn from circulation by the manufacturers.

HONORS TO M. PASTEUR.—King Humbert, of Italy, has decorated M. Pasteur. The Academie de Médecine has voted the sum of $2,000 for the projected Pasteur Institute.

LEGAL EXPENSES OF THE NEW YORK COUNTY MEDICAL SOCIETY.—Considerable grumbling is heard over the legal expenses of the County Medical Society. Out of an income of about $4,500, nearly three-fourths went last year into the pockets of the lawyers, the total sum paid them being $3,067.40. A natural inquiry arises as to whether there is any return, aside from the fines paid by quacks, for this extraordinary expenditure. If the sum of $3,000 were annually applied to encouraging scientific work or creating a building fund there would be very little complaint, but the doctor is apparently compelled to pay twice for the enforcement of the laws.

A NEW FIELD OF JOURNALISTIC ENTERPRISE is being opened by the local newspapers. It consists in furnishing as news long notices of the lives and successes of certain doctors. An illustration of this is seen in a newspaper published at Westport, Conn., in which a fulsome description of the attainments and skill of a local physician is given. A curious feature in these quack advertisements is that the quack is always anxious to let people know that he has at one time been associated with and taught by eminent and reputable physicians.

COMMENCEMENT OF THE BELLEVUE HOSPITAL MEDICAL COLLEGE.—The twenty-fifth annual commencement of the Bellevue Hospital Medical College took place on March 15th at the Carnegie Laboratory. The address to the graduating class was delivered by Dr. Isaac E. Taylor, the President of the College. Professor Dalton delivered an address in which he eulogized the late Dr. Austin Flint. Diplomas were presented to 139 graduates. The successful candidates for appointment in the Bellevue Hospital were: Hezekiah S. Houghton, Thomas McCann, Witter K. Tingley, and William H. Nammack.

THE GERMAN GYNECOLOGICAL SOCIETY holds its first annual meeting in Munich June 17th to 19th of the present year.

TRICHINOSIS IN BERLIN.—Dr. Grawitz, Virchow's second assistant, who gives the course in pathological histology for Virchow, says that about one-third of the cases diagnosed in life as muscular rheumatism are shown, by post-mortem examination, to be trichinosis.—Cor. *Medical Press of Western New York.*

A NEW EMMENAGOGUE.—This is "erotic excitement," and is certaialy in its ordinary form as venerable as the vertebrates. But a correspondent of the *Medical Press of Western New York*, Dr. T. D. Strong, suggests producing it in a scientific and perhaps subconscious way by applying sinapisms to the breasts.

PRAIRIE ITCH is the expressive title of a disease which seems to be prevalent in Texas, Kansas, and other Southwestern States. It is probably due to a parasite, but the editor of the *Kansas City Medical Index* confesses to ignorance of the pathology, while he prints a recipe for its cure, viz., the external use of a solution of sulphuret of potassium, gr. xx. to ℥ j. of water.

A PURE PEPTONE, prepared from milk, has been manufactured by Herr Weyl, of Berlin. It is a colorless powder, soluble in water, and of a not unpleasant taste. Senator speaks highly of it in phthisis and convalescence from typhoid fever.

MEDICAL EDUCATION IN CALIFORNIA.—*The Pacific Medical and Surgical Journal* takes some exception to our criticisms upon the state of medicine and medical education in California. The University Medical College and Cooper Medical College require, we are told, a "scholastic examination" before the Dean prior to matriculation, and three regular courses of lectures. We are very glad to learn that the preliminary examinations have been established, and to testify in general to the excellence of the two schools in question. According to the announcements of 1883, no such examination was required, unless evidence of a fair English education be considered a "scholastic examination."

Restricting the Practice of Vivisection in Austria.—Baron Conrad, the Austrian Minister of Public Instruction, has sent to the medical faculties a circular concerning vivisection. Henceforth it will only be permitted in very exceptional cases, when it is thoroughly necessary, and for important researches. Vivisection can be practised in Government medical institutions only, and then by the professor or *agrégés*. The animals must be previously rendered insensible.

Diphtheria in New Orleans has been on the increase in the past few years. In 1885 there were 166 cases reported, with 151 deaths! This shows not necessarily a high mortality rate, but a great neglect in diagnosticating and reporting the cases.

Surgeon William A. Corwin, United States Navy, died on board the steamer Adams, at Panama, on the 10th inst.

Medical Advertising in California.—Much discussion has recently taken place in the San Francisco County Medical Society, says *The Pacific Med. and Surg. Jour.*, relative to the extent of advertising that is permissible to medical men. The conduct of a member had been called in question because he placed a card in the programme of a variety theatre, calling attention to his attainments and his preference for certain diseases. This was naturally objectionable to the members of the society, but when the case came up for discussion the business cards of many practitioners were produced, including those of specialists, such as oculists and aurists, to prove that advertising is to a certain extent permissible to medical men, and therefore the question became one of degree.

Getting a Little Mixed.—Dr. Carl L. Jensen has discovered a way of manufacturing a certain form of pepsin, and has got a patent on it. The *Medical and Surgical Reporter* defends the right of a doctor to take out a patent. The Code says that it is derogatory to professional character for a physician to hold a patent for any surgical instrument or medicine. Our ochre-bound contemporary defends the Code and defends the doctor with his patent.

Embalming the Dead.—A bill has been introduced into the Rhode Island Legislature providing that no undertaker or other person shall apply to the body of any deceased person, or still-born child, any embalming or otherwise preserving or disinfecting preparation whatever, without having first obtained the consent of the friends of the deceased, and the written permission of the officer having custody of the returns of death in the town or city where the death occurred. The object of the bill is to prevent the hiding of criminal or suspicious appearances of bodies. It is supported by the health officers, but opposed by undertakers.

A New Form of Blackmail.—Two prominent physicians of Chicago have recently had civil suits brought against them for alleged damages in sums of $5,000 and $6,500, the real animus being, so far as known, the fact that the doctors had sued for the collection of their bills. Inasmuch as it only costs six dollars to commence such a suit against a physician, with no further liability to the plaintiff—whatever may be the result—this appears to be a cheap sort of revenge.

The Funeral Services of the Late Dr. Austin Flint were held at Christ Church, on March 16th. The church was crowded with the friends, colleagues, and pupils of the deceased physician. Hardly a prominent medical man in the city was absent, and the gathering was a remarkable and spontaneous tribute to the memory of the departed. The services were brief and simple.

The Cartwright Lectures.—Dr. William Osler began the delivery of the Cartwright lectures at the Young Men's Christian Association Hall this week. He has chosen for his subject certain questions in the Physiology and Pathology of the Blood.

Obituary.

AUSTIN FLINT, M.D., LL.D.,

NEW YORK.

Dr. Austin Flint died on March 13th, at his residence in this city, of cerebral apoplexy. He had been feeling in his usual good health, and on the day before had attended to his usual professional duties. On midnight of March 12th he uttered a cry and fell on his bed unconscious. He remained in an unconscious state for the next fourteen hours, when death took place. Drs. E. G. Janeway, Isaac E. Taylor, and William T. Lusk were called in consultation, and every effort was made to restore consciousness and avert the fatal issue.

Dr. Flint was born in Petersham, Mass., in the year 1812. He came of a race of English and American physicians. His great-grandfather, grandfather, and father, were medical men, and all obtained more than average eminence. Dr. Flint was educated at Amherst, and afterward graduated in medicine at Harvard in the year 1833, at the age of twenty-one. The first three years of his professional life were passed at Northampton and Boston. In 1836 he went to Buffalo, where he remained until 1844, his prominence at that time securing him a call to the chair of Institutes and Practice of Medicine at the Rush Medical College, Chicago. After a year of that life he returned to Buffalo, where he established the Buffalo *Medical Journal* in 1846, which he conducted for ten years. Meanwhile he was increasing his usefulness in various directions. He was one of the three founders, in 1847, of the Buffalo Medical College, at which, until 1852, he occupied the chair of the Principles and Practice of Medicine. Then he went to the Louisville University, holding the same chair in that institution, where he remained until 1856, when he went back to Buffalo as Professor of Pathology and Clinical Medicine. While still holding a residence at Buffalo he passed the winters of 1858, 1859, and 1860 at New Orleans, where he was Professor of Clinical Medicine in the medical school, and was also visiting physician to the Charity Hospital. He changed his home toward the close of this engagement to this city, where he has since remained. In 1861 he became one of the physicians to Bellevue Hospital and was appointed to two Professorships—the Principles and Practice of Medicine and Clinical Medicine at Bellevue, and Pathology and Practical Medicine at the Long Island College Hospital. He remained always with the Bellevue Faculty, but his duties forced him to sever his connection with the Brooklyn college in 1868. In 1872 he was elected President of the New York Academy of Medicine, from which Society he lately resigned.

He continued his connection with the New York County Medical Society, although he was active in the County Association. In 1876 he was a delegate to the International Medical Congress at Philadelphia, where he delivered an address on "Medicine." He attended the Congress at London in 1881, and at Copenhagen in 1884, and had been chosen President of the next Con-

gress, to be held at Washington in 1887. During the winter he was accorded the honor, never before received by an American physician, of an invitation to address the British Medical Association on "Medicine" at its coming meeting. The invitation had been accepted, and he intended to go to Europe in July for this purpose. In 1884 he was President of the American Medical Association. Dr. Flint was a member of a very large number of learned societies in this country and Europe.

As an author Dr. Flint did much for the profession. His "Treatise Upon the Principles and Practice of Medicine," published in 1866, has run through seven editions. Dr. Flint was engaged during the past winter in revision work for another edition. The sales of this book have been phenomenally large, reaching nearly 40,000 copies. A work on "Clinical Study on Heart Sounds in Health and Disease," which he wrote in 1852, received the first prizes of the American Medical Association in 1852 and 1859. His work on "Phthisis," and his "Manual of Percussion, etc.," have long been standard works.

Dr. Flint's real success as a practitioner, and his conspicuous prominence as a teacher and writer, began when he came to this city in 1861. He added lustre to the profession of this city, which in turn was always keenly awake to his merits.

Dr. Flint had never shown any signs of physical decline, or of the approach of senility. His voice was fresh, his step active, and his mental faculties as acute as ever. He had kept up his work of teaching, writing, and practising. It is said that he dreaded a lingering illness; a wish that he might be taken suddenly when his time came was often expressed by him.

At a meeting of the Faculty of the Bellevue Hospital Medical College, held March 15, 1886, on motion it was

Resolved, That this Faculty keenly sympathizes with the wife, son, and family of our lamented confrère, Professor Austin Flint, in their irreparable loss of a tenderly devoted husband, father, and counsellor;

Yet, that in their griet they will find consolation in that they can ever cherish the memory of his spotless life, his greatness, and his goodness;

That the son, grandson, and great-grandson of eminent physicians and surgeons, entrusted by nature with medical skill and sagacity, so nobly fulfilled his mission;

That his powers of thought and action were preserved in their fulness of vigor to the close of his intellectual and benevolent career;

That his prayer was granted in being spared from lingering illness;

That, as he had mitigated the sufferings of others, he himself was saved from suffering;

That after a day and evening of arduous medical duties, he retired to his painless couch of death;

"God's finger touched him, and he slept."

Resolved, That this Faculty has been deprived, in this dispensation of Providence, of one of the most illustrious founders of this College, whose professors felt honored by having their names enrolled with his; one through whose instrumentality other medical colleges have been established in our country; one whose pupils fill chairs in our Faculty, while others hold distinguished positions in similar institutions of medical instruction; one whose self-sacrificing and gratuitous services have been cheerfully rendered to the sufferers in Bellevue Hospital, and other hospitals in our city and country, for the last half century.

Resolved, That our city and the world have lost in his death one whose noble presence and tender sympathies in the sick-room cheered the heart and secured the confidence of the afflicted; whose remarkable record is justly the pride of any profession in any land; whose gifts and labors were recognized at home and abroad; who was honored with positions of distinction in America and Europe rarely won; from whose eloquent lips thousands of students in many colleges have been taught the science of medicine, and by whose graphic pen tens of thousands have gained medical knowledge; and whose numerous and valued works, translated into many tongues, will continue as fountains of instruction to future generations.

Resolved, That while our heads bow in grief at his sudden death, our hearts rise in gratitude to God for his prolonged life of widely extended usefulness.

Resolved, That a copy of these resolutions be engrossed and transmitted to his family, and that they be given for publication to medical and secular journals of this city.

ISAAC E. TAYLOR, M.D.,
President.

JOSEPH D. BRYANT, M.D.,
Secretary pro tem.

SAMUEL OAKLEY VANDER POEL, M.D.,

DR. SAMUEL O. VANDER POEL died in Washington, on March 12th, while on the way South for his health. His death was a surprise to the community, as he had not been thought to have any malady likely to have a fatal issue.

Dr. Vander Poel came of a family long distinguished in the affairs of this State. His father, also a physician, carried on an extensive practice at Kinderhook, Columbia County, N. Y. That was the doctor's birthplace on February 22, 1824. Equipped with an academic education in that town, the young man took a course at the University of the City of New York, of which Theodore Frelinghuysen was then Chancellor. Then he returned home, and for a while studied medicine with his father. This prepared him for entrance to Jefferson Medical College, in Philadelphia, from which he was graduated in 1845. The ensuing two years he passed with his father. His ambition looked beyond a lifetime in the quiet of Kinderhook, however, and in 1847 he went to Paris. French feeling was then revolutionary, and as the scenes of turbulence were not suitable for quiet study, he went for a time to Southern France and Italy, going back to Paris when quiet was restored in the summer of 1848. In 1850 he came home and settled in Albany, where he married.

Dr. Vander Poel had acquired a large practice when, in 1857, Governor King appointed him on his staff as Surgeon-General. In 1860 he became President of the Albany County Medical Society. The duties of Surgeon-General had been barely more than nominal during Governor King's administration, but in 1861, when Governor Morgan selected him for that place on his staff, the requirements and responsibility of the position were great. Without experience in organization, Dr. Vander Poel was called upon to create and manage a bureau of medical supply for all the troops sent out by the State. He had to keep about seven hundred positions filled with competent officers, and to deal with the most exacting class of men. The novelty of army and hospital service wore off while Dr. Vander Poel's position was yet new, and its difficulties were complicated by wholesale resignations. During one week he had to make five hundred appointments to fill vacancies by resignation. He filled the difficult position so acceptably as to win the thanks of the Governor and the Legislature, and when the work was over there was not a trace of bitterness in any quarter as a result of anything he had done. After the war he resumed private practice, which grew during the next few years until it became beyond question the largest in Albany. In 1867 he was chosen to the chair of General Pathology and Clinical Medicine at the Albany Medical College, and at about the same time he became one of

the Board of Managers of the State Lunatic Asylum, at Utica. He was elected President of the State Medical Society in 1870. While still devoted chiefly to his private practice, Governor Hoffman appointed him in 1872 Health Officer of this port. Quarantine matters were then in a deplorable state, and Dr. Vander Poel's powers of organization were again called into play. By introducing system into the management of the office and relaxing oppressive enactments, while still watchful for all needed sanitary regulations, the Quarantine was sustained for the first time in its history by commerce during his administration. He continued as Health Officer until 1880, and left the office with the regrets of the merchants and others who had been brought into official or personal relations with him. During his term he filled, in 1876, the chair of the Theory and Practice of Medicine in the Albany Medical College. After his term as Health Officer he returned to Albany for a year, but in 1881 he came here to live, and has since practised here. In 1883 he was elected to a Professorship of Public Hygiene in the medical department of the University of New York, from which institution he received the degree of LL.D. in 1884. He was also a member of the International Medical Congress, at Copenhagen, Denmark, in 1880–84.

Reviews and Notices.

Text-book of Ophthalmoscopy. By Edward G. Loring. Part I.: The Normal Eye, Determination of Refraction, Diseases of the Media, Physiological Optics, and Theory of the Ophthalmoscope. New York: D. Appleton & Co. 1886.

Of all the many persons attracted during the present generation to the special treatment of the eye no one is, perhaps, more competent to write a text-book of the ophthalmoscope than the author of the work before us. He has entered upon the task with the inspiration of the enthusiast, without which scientific work can at best be but mediocre, and the reader feels sure that nothing of importance has been omitted, and that the subject has been treated with the clearness its importance demands. In the introductory chapter we find the scope of the book thus announced: "In the whole history of medicine there is no more beautiful episode than the invention of the ophthalmoscope, and physiology has few greater triumphs. With it, it is like walking into nature's laboratory and 'seeing the infinite in action,' since by its means we are enabled to look upon the only nerve in the whole body which can ever lie open to our inspection under physiological conditions, and to follow in a transparent membrane an isolated circulation from its entrance into the eye through the arteries to its exit in the veins. We are further enabled to watch and study daily, or even hourly, morbid processes in each and every phase, from simple hyperæmia to absolute stasis, and from passive œdema to the most violent inflammation; while oftentimes through its agency, also, we get the first intimation of disease in remote and seemingly unconnected organs, so as to read as if in a book 'the written troubles of the brain,' the heart, the spleen, the kidneys, and the spine."

If we may not attach the importance to the revelations thus claimed for the ophthalmoscope, we can certainly attest to the frequency with which it has been found to confirm the diagnosis after other phenomena than optical have become pathognomonic.

The instrument itself is described in the appendix, and it is well known that Dr. Loring is the inventor of one of the very best combinations in use. The theory of the ophthalmoscope, and directions for its use, together with a brief and simple explanation of the elements of optics, is also to be found in the appendix.

Twenty pages are devoted to the anatomy of the fundus of the normal eye; sixty-two pages to its appearances under the ophthalmoscope and its anomalies; forty pages to the determination of the optical condition of the eye—refraction, astigmatism, etc. Forty-eight pages are given to the examination of the media of the eye—the aqueous humor, the iris, the lens and its opacities, vitreous humor, fundus, and to entozoa. The appendix consists of sixty-four pages.

An exhaustive review of a work of this kind would be beyond the scope of a weekly journal; indeed, it is so concisely written that no mere abstract would do the author justice. When it is stated that its literary excellence is in the author's best style, the method of investigation painstaking and exact, but little remains to be said in its praise.

The work is enlivened by good pictures; there are four excellent chromo-lithographic plates, and one hundred and thirty-one engravings and diagrams, all of which are well adapted to illustrate the text, many of them being original.

A Treatise on the Diseases of Infancy and Childhood. By J. Lewis Smith, M.D. Sixth edition, pp. 870. Philadelphia: Lea Brothers & Co. 1886.

Dr. Smith's wide and varied experience has made him an authority in children's diseases. His process of observation, coupled with a practicality which prevents him from becoming too much entangled in theory, has enabled him to write a book which practitioners have properly held for a long time in high estimation. Five years have elapsed since he put forth the fifth edition of the work now before us. A half a decade in these days of persistent research and investigation gives an author no easy task in the pruning, amending, and enlarging of his work. Some important maladies have been entirely rewritten, such as cerebro-spinal fever, scarlet fever, pseudo-membranous croup, and infantile diarrhœa. The treatment of many of the diseases has been revised.

Tablets of Anatomy. By Thomas Cooke, F.R.C.S. Eng., B.A., B.Sc., M.D. Paris; Senior Assistant Surgeon to the Westminster Hospital, and Lecturer at the School of Anatomy, Physiology and Surgery. Fourth Edition. London: Longmans, Green & Co. 1885.

In these "Tablets" a student will find great assistance in helping him to recall the anatomical relations of the various parts preparatory to examination, and the practitioner also whose memory is somewhat treacherous will be enabled to refresh it in a moment by glancing at the tables spread out clearly and distinctly before him.

How We Treat Wounds To-day. A Treatise on the Subject of Antiseptic Surgery which can be Understood by Beginners. By Robert T. Morris, M.D., late House Surgeon to Bellevue Hospital, New York, etc. Pp. 161. New York and London: G. P. Putnam's Sons.

The title of this little book indicates precisely its scope and intent. The author has done his task well. In language terse and in aphorisms pungent Dr. Morris defends antiseptic surgery, and offers directions for its application in every-day practice which are evidently the outcome of actual observation. Although the language is somewhat enthusiastic, the picture is not overdrawn, and the results of Lister's great innovation are carefully considered.

Its clear instructions for the preparation of the dressings (giving even the cost and place for purchasing) will enable the general practitioner who is removed from the great cities to provide for emergencies, and the author's incisive method of impressing the principles and practice of "genuine antisepsis" will render the intelligent physician so watchful and exact in its execution that very soon "he will find himself proud of his results." The antiseptic treatment of all wounds is minutely detailed under their respective titles—open, lacerated, etc. Hence the practitioner need only refer to the proper chapter to find himself complete master of the situation.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, Monday, February 8, 1886.

STEPHEN SMITH, M.D., CHAIRMAN.

DR. R. F. WEIR read a paper (see p. 321) on

THE TREATMENT OF VARICOCELE.

DR. ROBERT ABBE agreed with Dr. Weir's conclusions almost entirely, and he would, therefore, confine his remarks to the incidents connected with the operation. A radical cure was not always accomplished by simple ligation of the veins subcutaneously with catgut. It was in most cases accomplished where the varicocele was not a large one. But, as Dr. Weir had shown, there were several veins, and while the ligature shut off the main one, it sometimes occurred that the others became dilated, and thus there was a recurrence of the varicocele. He had seen this in two or three cases. Regarding the safety of the operation by subcutaneous ligature, he thought that was a very important matter. Although he knew of no recorded death, the operation in a considerable number of cases was certainly attended with unpleasant complications. We would like to be able to assure the patients that they could go out to their work within eight or ten days, but in the majority of cases they could not. Often two or three weeks, and even four or six weeks, elapsed before they could be discharged cured. Sinuses occurred at the seat of the ligature which sometimes required weeks to heal by granulation. There was also a complication which Dr. Weir did not speak of, and which Dr. Abbe had observed in a considerable proportion of cases, namely, an induration of the epididymis and testicle; a sort of subacute epididymitis and orchitis. This might occur, however, after other methods of operating. But it followed simple ligation, and also more complicated operations. He presumed it was due to tardy return of blood which was transmitted to the organ through the artery of the cord after the spermatic artery had been occluded by the ligature. The induration might take place during the first three or four days, or it might not come on for a week or ten days.

Dr. Abbe gave the results of operations for varicocele in St. Luke's Hospital during the past ten years. There were thirty-six cases in all. The method at first used was Wood's, described in the paper of the evening. Sixteen cases were treated by this method, of which four, not resulting in complete cure, were operated upon within a month by amputation of the scrotum. The antiseptic catgut ligature was employed subcutaneously in six cases, of which three were followed by ablation. The antiseptic silk ligature passed at two places was employed in one case. There was amputation of the scrotum alone in six cases, and amputation with ligation of veins in seven cases. The testicle and vas deferens were inflamed in four cases after Wood's method. In the case in which the silk ligature was employed there was epididymitis. Of the six cases treated by catgut ligature one had epididymitis. After amputation and the use of catgut there was epididymitis in all of the seven cases. There were abscesses in a number of cases in both the simple Wood's method and the open operation.

It seemed to Dr. Abbe we should be specially careful in the open operation in handling the parts. And we should not amputate too much of the scrotum; not as much as if we were going to rely upon amputation alone for a cure; for, by crowding the testicle up into an unnatural position, perhaps twisting the vessels, we shut off the vein and artery of the testicle for a time at least, and caused danger.

He recalled two recent cases in which the epididymis and testicle, becoming indurated, gave him some anxiety for a time, for he feared gangrene of the testicle or sloughing. They both came out nicely, however, although for more than four weeks the organ lay embedded in a solid inflammatory mass. In one similar case a slough took place, which, as near as he could ascertain, occurred in a portion of veins lying between two ligatures. That, however, was a sequel to a secondary hemorrhage taking place within twenty-four hours after amputation of the scrotum, although he thought he had left the wound perfectly free from danger of hemorrhage. He opened the wound, evacuated a quantity of clot, ligated the small bleeding vessel, and the case did well except for the slough mentioned.

DR. M. H. HENRY had been interested in the paper read by Dr. Weir, in which he gave an account in a very terse and elegant manner of the procedures that had been adopted for the cure or relief of varicocele. He supposed it would be just as well to begin with the relation of his personal experience, which commenced about 1856, consisting at first in observing what others did. About 1860 Dr. Henry performed Ricord's operation, but without very good results. He was always struck with the uncertainty of a cure when ligatures were employed. There was no doubt then, and there is no doubt to-day, in his own mind, that the ligation of the veins was dangerous, not only to life, but it was liable to be followed by atrophy of the testicle, and of being unattended by any beneficial result. Now, one of the greatest inconveniences from which patients suffering from varicocele complained was that the length of the scrotum interfered with the crossing of the legs and with assuming other positions. Ablation of the scrotum would do away with this. Any of the other operations described by Dr. Weir, subcutaneous ligature, ligature and ablation of veins, and ligature with ablation of the scrotum, were regarded by Dr. Henry as dangerous. Complete ablation without ligature would cure the varicocele, and if performed after the manner which he had adopted and described, it was the best and safest operation. Dr. Henry claimed nothing new with regard to the method excepting that he had made it safe. He described different clamps which had been employed for taking up the redundant tissue during the operation, and then showed the superiority of his own. He excised all redundant tissue, putting the testicle in the same position which it occupied when exposed to cold, and inasmuch as the scrotal tissue had been so greatly stretched, he did not think there would be danger of elongation from further resiliency. Cases which he had operated upon many years ago showed a complete cure. In 1880 he read a paper before the Academy, giving the results of his treatment, and the method had been employed more or less by different operators. Dr. Henry had noticed that most cases of varicocele occurred in persons of delicate health. He had never seen a case of severe varicocele without a redundancy of scrotal tissue which required to be removed, and if we followed this procedure we would not be troubled with abscess, following the use of the ligature, and other unpleasant symptoms which attended other methods described. In three of his cases the varicocele had been accompanied by hydrocele. One of these cases he saw twelve years afterward, and there had not been any return of the hydrocele.

The clamp employed by Dr. Henry was easily adjusted, never slipped, and formed, as it were, an artificial raphe corresponding to the normal raphe in the scrotum.

DR. CHARLES MCBURNEY had treated a good many cases of varicocele in both hospital and private practice, and his treatment had consisted of three different methods. The first was adopted a good many years ago, before he had become thoroughly acquainted with antiseptic surgery, being the use of Wood's clamp described by the author of the paper. The results were satisfactory; indeed, he must say very much so, except that the instrument itself was uncomfortable. There was some

suppuration in the track of the wire. The second method consisted in a combination of Wood's clamp with amputation of the scrotum, and was employed where there was a redundancy of scrotal tissue. The third method was the use of the subcutaneously applied catgut ligature. This he had used in a good many cases since 1880, and with the greatest satisfaction. It was very easily applied, it caused no distress in recovering from the anæsthetic. He had employed it without an anæsthetic and without causing discomfort. He had never seen suppuration follow its use, and the results in general had also been positively satisfactory as regards cure. He had never resorted to excision of the veins, and at present he did not look forward to excision of the veins in varicocele as an excellent measure. If all we desire to accomplish was simple occlusion of the veins, he thought the skilful application of the ligature would be sufficient, and the subcutaneous catgut ligature would answer this purpose admirably. That one could fail to apply the ligature in a manner to include all of the veins, was undoubtedly true. But he would, he thought, always make use of this method in preference to the open one, as he could hardly see how the latter offered a greater probability of occluding the veins.

As to ablation of the scrotum, he thought all surgeons would agree that where there was a redundancy of the scrotum it was desirable to effect suspension, and the most satisfactory way was, of course, to shorten the scrotum itself. But he could not agree with Dr. Henry's conclusions with regard to the effect of amputating the scrotum. Dr. McBurney had seen varicocele in cases in which there was no elongation of the scrotum, and probably had never been. It would have been difficult to say whether one testicle was lower than the other. He had seen one case—and it carried with him a good deal of weight—in which the varicocele returned after perfect suspension by ablation of the redundant scrotum. To be sure that was only one case, but that case was sufficient to satisfy him that amputation of the scrotum alone was not always a cure for varicocele. Where the scrotum was elongated and the testicle was unsupported, Dr. McBurney thought amputation was better than artificial support, and the instrument invented by Dr. Henry for amputation was better than any other which had been recommended.

Dr. George A. Peters had employed the best method in use at different periods during his surgical career. At one time he used Wood's clamp, and his experience with it had been very satisfactory. Occasionally he had suppuration, but he learned to have less and less the oftener he did the operation. The great trouble seemed to be to know just when to remove the wires. At first they were left too long, and afterward he sometimes removed them too soon, but in general the results had been quite satisfactory. Subcutaneous application of the catgut ligature, however seemed to have given even better results than Wood's clamp. Dr. Peters had amputated the scrotum a number of times, but he had not done both operations on the same patient. He thought, however, he would associate ablation and ligation hereafter. He should say that it seemed to him ablation did not offer as good a chance for a cure as ligation. But where there was redundant scrotum, requiring the use of a suspensory bandage, he would amputate.

Dr. A. M. Phelps, of Chateaugay, N. Y., by invitation, said he had been much interested in the discussion of the question of the treatment of varicocele. He had had some experience with the different methods described, and, as had been said by others, he had had some good results and some bad. He was rather in favor of removing as much of the scrotum as possible, and at the same time ligating the veins. He had had only one case in which there was bad suppuration, and there it was probably because due regard was not paid to antisepsis.

The Chairman thought from his own experience that the truth probably lay somewhere between the extreme opinions which had been expressed. There was no question at all, he thought, but what varicocele might exist without an elongated scrotum. He had seen that in several instances. In such cases, of course, amputation would not be the remedy. Ligature with catgut had given the best results, and it could be used without danger, excepting, perhaps, that of induration of the testicle alluded to by Dr. Abbe. Immediate bad effects he thought had been avoided almost entirely. But when there was elongation of the scrotum he thought there was no question at all but what amputation was best, and Dr. Henry's instrument was much the best he had ever used. He took the ground, in practice, of resorting to whatever method seemed best suited to the case. It seemed to him there was a class of cases in which both amputation and ligation were required.

Dr. Weir said, with regard to subcutaneous ligature of the veins, we should not go too close to the testicle. The open wound had the merit of quickness, and in hospital practice, where due care could be given to the case, treating it antiseptically, it had advantages, but for general practice he would not advocate it. He fell back on simple ligation for small varicocele, and in other cases amputation with a certain amount of ligation. We were liable to make the error of using too many ligatures. As to amputation of the elongated scrotum alone, it was not so reliable. Absolute cure of the varicose condition by ablation was extremely rare.

Dr. Stephen Smith was elected Chairman, and Dr. A. B. Judson, Secretary, for the ensuing year.

The Section then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 27, 1886.

John A. Wyeth, M.D., President, in the Chair.

The special subject for the evening was

INTESTINAL VOLVULUS,

and the discussion was opened by Dr. R. Van Santvoord with a paper (see p. 329).

ELONGATED AND DISPLACED SIGMOID FLEXURE.

Dr. L. Emmett Holt presented a specimen with the following history: It was taken from the body of a child aged thirteen months, who had died of pyelo-nephritis. The only symptom during life which seemed to bear any relation to the displacement was a persistent tympanitis, which had existed for months, and was much of the time excessive.

On the autopsy the sigmoid flexure occupied the umbilical region and was much distended with gas, so that it resembled the stomach. The descending colon was normal in size and position, but at the crest of the ilium the intestine was slightly twisted upon itself and passed in front of the small intestine to the right of the median line, and descended into the pelvis near the *right* sacro-iliac junction. The sigmoid flexure measured ten inches in length, being longer than the descending colon. Its mesentery was much elongated, but its walls, except a degree of attenuation from the distention, showed nothing pathological.

The case was an illustration of a condition not very unfrequently seen, and undoubtedly having an influence in the production of volvulus, though that condition could hardly be said to be present, as neither vomiting, constipation, nor any other signs of intestinal obstruction had existed.

The President said that one of the chief points of interest in this class of cases was with reference to surgical interference in intestinal obstruction from any cause. He believed that the rule should be, not to wait even twenty-four hours when there were well-marked symptoms

of obstruction. It would be wiser to explore at once—which, under ordinary circumstances, was not a dangerous procedure—and then a positive diagnosis could be made, and in most cases the obstruction removed. If the exploratory incision is made within twenty-four hours, it is not dangerous, and all obscure points which cannot be made out by any other method can be solved.

With regard to puncturing the intestine, either after it had been exposed or through the abdominal walls, Dr. Wyeth had punctured hernial sacs in two cases. The punctures were made simply for the relief of pain, due to distention, in hopeless cases, and in each instance he had an opportunity to examine the intestine at autopsy, and found that the holes had remained open so that the contents could still escape through them, although it was several days after the punctures were made before death took place.

Dr. Van Santvoord said that the probable reason why the punctures did not remain open in his case was because the cæcum was immensely distended, and with the collapse of the gut there was a corresponding diminution of the size of the openings. The use of a small needle in a hernial mass was somewhat different than its use in a largely distended intestine through a distended abdomen. It is a fact well established that these punctures have been followed by extravasation of fæces and peritonitis, and their use through the unopened abdomen is discouraged by Mr. Tait.

Dr. Wesley M. Carpenter referred to an act which was played in the same amphitheatre in which the Society was then holding its meeting. The late Dr. Willard Parker was lecturing on strangulated hernia, and mentioned the embarrassment which sometimes attended the escape of several coils of intestine from the abdominal cavity. This condition of things was illustrated by a striking picture.

With regard to the treatment which the protruding intestinal coils, under such circumstances, should receive, he spoke of the temptation which might arise to puncture them, but emphatically warned the students against yielding to the temptation, because of the great liability to the escape of intestinal contents and the development of peritonitis.

After Dr. Parker had passed this point and got well toward the close of his lecture, the late Dr. Alexander H. Stevens entered the amphitheatre, and before the hour expired, Dr. Parker invited him to make some remarks to the class. This venerable surgeon said that he did not know that he had much to add to what he had heard on the important subject of the lecture, but his attention had been attracted to the very embarrassing condition of things illustrated by Professor Parker's diagram on the wall, and he would like to say that the very best plan of treatment of the distended gut, under such circumstances, was to make numerous punctures with a fine cambric needle and allow the gas to escape, when the intestine could be easily returned to the abdominal cavity and no harm would follow the operation.

Whereupon Dr. Parker smiled, the students smiled, the bell rang, and the class was dismissed.

Here were given, by two of the great surgeons of this country, opinions which were directly opposed to each other, and many a confiding medical student saw for the first time an illustration of the adage, "Great men will differ."

From the number of cases in which puncture of the intestines, either after they had been exposed or through the abdominal walls, has been done without consequent harm, one might be led to resort to it without hesitation; but there is a sufficient number of cases on record in which these punctures have been followed by evil results to warn us against their indiscriminate use.

Dr. J. Lewis Smith asked the President if he would resort to an early operation in ordinary intussusception occurring in an infant. He had succeeded in reducing intussusception with injections of water as late as the third day. He had no doubt, however, that many lives might have been saved by operation, but thought that, perhaps, an exception with reference to intussusception might be made, as to resorting to operative interference as early as indicated by Dr. Wyeth.

The President asked Dr. Smith what proportion of cases of intussusception had recovered where no operative interference had been made.

Dr. Smith said that up to the last four or five years the proportion of deaths had been very large. But he thought that he could now detect the condition early, and therefore be able to commence treatment within the first day.

The President said that the hopelessness of these cases after a few days called for reduction of the intussusception within twenty-four hours.

Dr. Smith said that unfortunately, in most cases in infants, purgatives had been given before the physician was called, and their action being pernicious, the obstruction was already so great and the invaginated mass so large, that it was difficult to reduce it. But with early diagnosis and the avoidance of purgatives, and treatment by injections of water, with kneading the belly, he thought that success might be obtained in perhaps one-half of the cases.

Dr. Van Santvoord said that Lichtenstein, if he recollected correctly, placed the mortality in intussusception at seventy per cent.

The President thought that large injections of water and distention of the intestine with gas, were equally as dangerous as the exploratory operation, and certainly not as positive with reference to diagnosis and result. He had come to this conclusion from the study of hernia cases. He did not believe that a patient with strangulated hernia would ever die, if operated upon within from *six* to twelve hours after the strangulation occurred, or at least the rate of mortality would be reduced to almost zero. He believed that it was from waiting that the disaster came in these classes of cases.

Dr. Smith had seen several cases in which he had been sorry that laparotomy had not been performed; one in particular, the specimen from which he had presented to the Society.

The President said that he operated four weeks ago on a patient with symptoms of intestinal obstruction, at the junction of the sigmoid flexure and the rectum. Not knowing what the exact condition of affairs was, he anæsthetized the patient, and performed linear rectotomy, passed his coned fingers up to the point of obstruction, pushed it up an inch or so, and, strange to say, relief of the obstruction at once followed. Although it was not then made out, he had regarded the case as one of prolapse of the sigmoid flexure into the rectum.

Dr. Holt had recently seen the report of two or three cases in which injections of water, two to three days after the obstruction occurred, resulted in perforation—showing that the method is not without danger, if the symptoms are acute and the obstruction tight.

Dr. Smith had not seen an ill result from the use of water, but had seen one case of rupture produced by inflation.

Dr. Boldt raised the question as to the use of opium in cases of severe pain and doubtful diagnosis; and referred to a case in which, after the administration of a hypodermic injection of morphine the pain was relieved and the vomiting ceased. The case was one of umbilical hernia, and the question was, would it have been preferable to have operated at once?

The President said that he should, in such cases, give morphine to relieve the pain, and then operate.

Dr. Van Santvoord thought it wise to keep in mind the fact that not unfrequently, according to the urgent symptoms present, it would seem that some kind of obstruction existed, but the patients were relieved entirely by injections of morphine. Within the last two years he had seen five such cases, in which he felt almost certain that some form of obstruction was present, and yet all

the symptons passed off under the influence of opium. It had been a growing impression with him that the cases of possible intussusception, or twisting of the gut, which subsided spontaneously, or with a single injection of morphine, were rather common. Moreover, it should be borne in mind that those who wrote on this subject were chiefly surgeons who saw severe cases, and therefore had a rather exceptional experience; of course, they are guided in what they say by what they see.

The President said that the symptoms mentioned in the cases referred to by Dr. Van Santvoord did not mean obstruction which would lead to exploration of the abdominal cavity. He thought there was no stronger argument in favor of surgical interference than the quotation made by Dr. Van Santvoord, that seventy per cent. of the cases of intussusception terminated fatally.

Dr. Van Santvoord said that the cases referred to in the quotation came from the records, while the slight cases did not get recorded at all.

The Society then went into executive session.

Stated Meeting, February 10, 1886.

John A. Wyeth, M.D., President, in the Chair.

Dr. L. Waldstein, Chairman of the Committee on Microscopy, reported that the specimen presented by Dr. C. H. Knight at the last stated meeting was

A SIMPLE FIBROMA

of the vocal cord, which did not implicate the mucous membrane proper.

Dr. T. Mitchell Prudden presented a specimen, with microscopic sections, of

CHRONIC LOCALIZED ENDOCARDITIS AND INTERSTITIAL MYOCARDITIS FROM INFLAMMATION AND PARTIAL OCCLUSION OF CORONARY ARTERY.

He was indebted for the epitomized clinical history to Dr. A. B. Pope, Resident Physician to Bellevue Hospital. Male, fifty-two years of age, United States sailor, single; mother died of phthisis; family history otherwise good; never had rheumatism; well-marked alcoholic history; seven years ago had sore and suppurating bubo, but no secondaries. Patient says that in wet weather he has slight cough; has had night-sweats and one hemorrhage from lungs. For some time he has had ringing in the ears and spots before the eyes. Six days before admission he vomited several times and began to have diarrhœa. He was admitted on January 6, 1886, cyanotic and suffering from severe dyspnœa. Heart-beats were regular but frequent (124), very feeble, no murmur. No tenderness or pain in chest. Examination of lungs showed good resonance, with some scattered crepitant and sub-crepitant râles, with few mucous râles. There was no œdema of feet or legs. The urine examination showed only water, no albumen. On January 9th he had less dyspnœa, but was "out of his head." The next day his craziness disappeared and his dyspnœa returned, but was somewhat relieved by opium. He continued to have attacks of very severe dyspnœa, with some symptoms of pulmonary œdema, and so died on January 18th, twelve days after admission, and eighteen days after the commencement of his attack. The temperature had ranged from 99° to 102°.

Autopsy.—Brain not examined.

Heart, right auricle and ventricle filled with a voluminous, loose red clot, pulmonary and tricuspid valves normal. Aortic and mitral valves show scattered patches of fatty degeneration, as does also the aorta. The left ventricle shows a patch of much-thickened endocardium, about five millimetres by seven millimetres, occupying the apex of the heart, and extending anteriorly and over the lower portion of the septum. The endocardium in some parts of this region is five millimetres in thickness. A dense, whitish blood-clot is entangled among the papillary muscles, and firmly adherent to the heart-wall at the point of lesion. The wall of the heart itself over the area corresponding to the endocardial lesion shows a replacement of its inner half by new, dense connective tissue.

The heart-muscle in this region is found by microscopical examination to present a moderate degree of fatty degeneration.

The coronary artery leading to the affected region shows, about two centimetres below its origin, a sudden constriction from the formation of a dense mass of new tissue in its walls. Below this, for about one centimetre, the artery is very narrow, the seat of obliterating endarteritis and atheroma, and is nearly occluded by a thin parietal thrombus.

Beyond this point the artery widens out, and with the exception of a few patches of fatty degeneration in its wall, appears normal.

The coronary artery leading to the right ventricle shows a small patch of atheroma near its origin.

Right pleural cavity contains about five hundred cubic centimetres of clear, yellow serum, with a few flocculi of fibrin. The pulmonary pleura over the upper lobe is covered with a thin pellicle of fresh fibrin. The upper lobe presents the appearances, both gross and microscopical, of lobar pneumonia in a condition of advanced resolution. The left lung presents general old pleuritic adhesions, and partial pneumonic consolidation in the lower lobe, similar to that on the right side.

Spleen shows moderate degree of chronic interstitial inflammation; kidneys are small with free capsule, slightly nodular surface, thin and irregularly marked cortex. Liver is normal.

He presented the case because the specimen showed in the most striking and evident manner the exact character of this always interesting and important heart lesion, and furthermore, because it afforded an excellent example of a class of cases in which persons go on enjoying tolerably good health, with very extensive lesions of an important organ, but succumb to the original disease when an intercurrent disorder disturbs the equilibrium under which the life functions were being fairly well maintained.

Dr. Wesley M. Carpenter asked if microscopical examination was made of the arterioles of the kidneys.

Dr. Prudden replied in the negative, and that the diagnosis of renal disease was based on the gross appearances.

Dr. Carpenter said he asked the question because, somewhat recently, there had been considerable discussion concerning the relation existing between fibroid degeneration of the arterial system and Bright's disease of the kidneys. He had examined the blood-vessels of kidneys removed from the bodies of persons who had given the ordinary history of chronic Bright's disease in a large number of cases, and in a goodly proportion of them had found no particular change in the arteries. These examinations were fairly reliable, although made in the ordinary line of pathological work and laboratory instruction. In other cases, however, in which persons had died with the usual symptoms of chronic Bright's disease, and in which the kidneys had furnished the lesions of chronic diffuse nephritis, the arteries exhibited very marked changes, not only in the external coat, but also in the intima. There were, therefore, according to his observations at least, exceptions to what perhaps, from what had been written, might be inferred to be the rule—namely, that fibroid degeneration of the blood-vessels was necessarily a part of the morbid anatomy of chronic diffuse nephritis.

Dr. Prudden could concur in Dr. Carpenter's remarks, but in this particular case the lesion in the coronary arteries seemed to be local; there was no general atheroma.

Dr. Carpenter said that was the reason why he asked concerning the blood-vessels of the kidneys. The case

seemed to be an illustration of the fact that such fibroid degeneration of the arteries might be local. The special point to be made was that fibroid degeneration of the blood-vessels or arterio-capillary fibrosis, was not necessarily a part of the morbid anatomy of chronic Bright's disease.

Dr. Louis Waldstein had found fibroid changes affecting the arteries in kidneys the seat of chronic Bright's disease, but he was not prepared to say that it was present in all cases. Its existence depended very much upon another factor, and that was the senile changes present in the body under examination.

It appeared to him that the examinations made by Gull and Sutton, and to which doubtless Dr. Carpenter referred, were mostly in elderly people, and that the changes described when the kidney trouble was found were senile in character. Fibroid change in the arteries might exist in various organs, without any change at all which could be properly regarded as belonging to Bright's disease. On the other hand, he had seen cases, as remarked by Dr. Carpenter, in which Bright's disease existed with fibroid changes affecting the blood-vessels, and especially those of other organs of the body than the kidneys.

With reference to Dr. Prudden's specimen, he had had occasion to examine the coronary arteries with fibroid change in two cases very thoroughly, and singularly enough, he did not find the changes which Dr. Prudden had described. Instead of proliferation of the connective tissue he found emboli and degenerative changes in the myocardium. In both cases there was the clinical history of repeated attacks of angina pectoris.

The President said the same point was brought out in the Society about two years ago, in connection with a specimen in which the condition referred to by Dr. Waldstein was found, but the symptoms were about the same as those given in Dr. Prudden's case.

Dr. Prudden believed it to be essential to separate sharply the cases of partial and complete occlusion of the coronary artery.

In one class of cases there is a sudden and complete obstruction of the coronary artery, followed by fatty degeneration of the myocardium that may lead to rupture, although rupture does not always occur. In another class of cases a thrombus occludes the artery, and from this small emboli become detached and find their way to other parts.

Furthermore, there is a class of cases in which there is only partial occlusion of the artery from thrombus, but there is subsequent connective-tissue proliferation.

In the specimen referred to by the President, it seemed to him that the heart-muscle had undergone degeneration, and afterward fibroid change took place; whereas in the specimen just presented there was a well-defined area which had probably not gone through the degenerative stage, but in which new connective tissue had formed from the beginning.

Dr. L. Emmett Holt presented specimens from a case of

ACUTE NEPHRITIS IN AN INFANT.

Dr. Waldstein asked Dr. Holt how he collected the urine from small children.

Dr. Holt said the best method he had employed was to place a clean sponge over the genitals and fasten the diaper over that.

Dr. Waldstein said he asked because he regarded it as very important to examine, as often as possible, the urine of children who give symptoms which cannot be grouped readily. About one year ago he was called suddenly, in the night, to see a child that was taken sick two days before, and when he arrived at the house, within a very short time from the call, the child was dead. The symptoms had not led the attending physician to suppose that the child was so ill. The post-mortem examination revealed morbid changes in the kidneys only, which were very much enlarged, and showed both interstitial and parenchymatous nephritis.

Dr. Waldstein had since read a paper by some German writer, who recommends the use of a catheter for collecting the urine in small children.

Dr. Carpenter said that wrapping the genitals and covering the abdomen suddenly with flannel wrung from hot water, had been suggested as an efficacious method of making children empty the bladder.

Dr. Boldt said he had adopted this method, and had found it successful in a large proportion of cases.

Dr. Holt said it was resorted to in his case several times and with good effect. He also regarded it as important to recognize a class of cases in which there is no retention, but a temporary suspension of the action of the kidneys, and this state of affairs might continue for twelve or twenty-four hours without apparent cause. One point of interest in his case was the fact that a child could have so extensive kidney disease and yet all the ordinary objective symptoms be absent.

Dr. J. E. Newcomb asked Dr. Holt if he had noticed any tendency to collapse in the use of antipyrin.

Dr. Holt said that he had used it in fifty cases in children, and had not seen the slightest tendency to collapse. In one case the drug was administered in a dose of ten grains without unfavorable symptoms.

Dr. Newcomb said that he knew of one case in which two grains, given to a child aged six months, produced an alarming collapse, from which, however, the child recovered.

The Society then went into executive session.

OUR LONDON LETTER.

[Regular Special Correspondence.]

MR. SUTTON'S LECTURES ON EVOLUTION IN PATHOLOGY — THE ORIGIN OF TUMORS — THE ADMISSION OF WOMEN TO THE MEDICAL PROFESSION — THE LATE MR. WORDSWORTH.

LONDON, February 25, 1886.

In my last letter I gave a brief *précis* of Mr. J. Bland Sutton's views on Inflammation, as expounded by him in his second "Erasmus Wilson Lecture" at the College of Surgeons. The subjects discussed by Mr. Sutton are so important that, at the risk of wearying your readers, I venture to devote some further space to give a short account of his third and concluding lecture. In this the etiology of tumors, or, as the lecturer preferred to call them, neoplasms, was treated of. Inflammation and tumors, although they may not, as some students think, form the whole, or even the greater part, of pathology, even from a surgical standpoint, are yet, at any rate, two subjects eminently interesting to every practitioner. I would not have it understood that Mr. Sutton's first lecture was one whit less interesting or important, but it dealt with matters less interesting to the clinician, so I have not given any report of it.

Mr. Sutton gave the following definition of a neoplasm: "A new growth characterized by histological diversity from the matrix in which it grows; it is distinguished from inflammatory new formations by the variety of its forms, its mode of origin, and the frequent inherent tendency it has to increase." He ranged neoplasms in three groups: 1, Mesoblastic, including the connective-tissue growths; 2, epiblastic and hypoblastic, comprising adenomata, carcinomata, and papillomata; 3, teratomata, or neoplasms containing tissues derived from the three embryonic layers. The histological details would determine the varieties.

Mr. Sutton went on to say that Cohnheim's hypothesis, which ascribed the origin of neoplasms to persistent rudiments, had the most to recommend it if the term "tumor" were used in its most restricted sense. This hypothesis

he proceeded to expound, and showed the immense number of facts which can be brought forward to support it. He was careful to explain that he used the term "germinal rudiment" in a more extended sense than that in which Cohnheim employed it. We had evidence, he said, that such germinal rudiments did exist, and that such germs might become tumors. No one disputed the origin of true cysts from functionless ducts and tubules, and why should the origin of solid neoplasms from rudiments be doubted, especially if such untransformed tracts of tissue could be demonstrated unequivocally to be heteroplastic in their nature? It was, of course, easier to demonstrate the origin of cysts from pre-existing germs than it was ever likely to be in the case of neoplasms, but still we could show that in the region where particular tumors were more prone to occur there was embryological testimony to explain why they occurred there. An epithelioma on the lip was what we expected, but a similar growth starting in the midst of a block of cartilage was incomprehensible. A piece of cartilage in the midst of the shaft of a femur of a boy five years of age was cartilage in the wrong place. Such islands were, nevertheless, to be met with by those who cared to expend time and labor in searching for them; and, as pointed out by Virchow, might in later life become the starting-point of enchondromata. The lecturer referred to the development of enchondromata (and also osteomata—the latter being simply higher developments of enchondromata) from those regions of the skull in which, even in the oldest, traces of the cartilaginous matrix remain. Such regions were the region immediately posterior to the external auditory meatus, the neighborhood of the nasal fossæ, the septum nasi, and the vertebræ, and these were favorite situations for enchondromata and osteomata. Moles and nævi might be regarded as tumor-germs. There were many instances of a small nævus, untreated in early life, forming later on an angioma of some size, and becoming a source of danger. All germs or rudiments did not become tumors. Three courses were open to them. They might (1) undergo transformation into normal tissue; (2) remain quiescent; (3) be stimulated into abnormal activity by irritation. If we admitted the origin of enchondromata, osteomata, and angiomata from rudiments, need we doubt the origin of other varieties of mesoblastic tumors from similar sources? There was this important fact—they were always confined to regions of the body where the elements of which they were composed were to be unequivocally demonstrated.

Referring to sarcomata, Mr. Sutton said he had no doubt that many cases of round-celled sarcomata were not genuine neoplasms, but the result of the irritation of micro-organisms. He alluded to a paper by Mr. Pearce Gould showing the apparent traumatic origin of many sarcomata, and mentioned several observations tending to the same conclusion which he had himself made on animals. Careful examination, he said, of many of these cases supported the notion that after the injury the inflammatory tissue, or tissue of repair, exceeded normal limits, developed erratically, and played the part of a tumor-germ.

The second group of neoplasms contained, in addition to mesoblastic tissue, epithelial elements derived from either the epiblast or the hypoblast, and in their structure more or less resembled glands. If the resemblance was close, the neoplasm was termed an adenoma, and the cells clothed the alveoli in a regular manner; but if the cells were merely tumbled in confusion into the alveoli, it was called a carcinoma. The distinction between hyperplasia of a gland and a glandular neoplasm was simple—the latter was impotent to produce the secretion normal to the gland. Carcinomata resembled secreting glands in their relation to blood-vessels, and in their mode of development. The abnormal epithelial growths in carcinomata mimicked the mode of development of glands by a down-growth of epithelium from the hypoblast or epiblast. There was no valid reason why the abnormal down-growths of epithelium occurring in the neighborhood of any glands, and forming carcinomata, should not be considered tumor-germs in the same sense as the little masses of cartilage lodged in the interior of a long bone. If we were asked why cancer should be more frequent in the old or debilitated than in the young or vigorous, the answer was that young trees brought forth the best fruit because in them vigorous growth was at an acme; when this faded, then that which was inferior was produced. So with glands. Irritation in the young produced papillomata; in the old, cancer.

After considering teratomata, and diverging from his subject proper to give a few words about congenital cervical cysts, Mr. Sutton concluded by saying that any one ambitious of becoming a scientific pathologist must first be a sound human anatomist, acquire a tolerable knowledge of comparative anatomy, and then keep well abreast of the teachings of embryology. These qualifications are so admirably combined in Mr. Sutton himself that he might have been accused of self-praise, were it not for his modesty. Given these qualifications, and the pathologist, he said, would then, in spite of himself, become a firm believer in the fundamental principles of the grand doctrine of "evolution."

No more striking proof of the mutability of human opinion could well be adduced (from a medical point of view) than the change of front made by many leaders in the profession in regard to the question of the admission of women to practice. At first vigorously opposed, then treated with contempt, their claims now meet with marked approval in many quarters. A great step was gained when the University of London threw open its doors to women, and a still greater gain was the extension of the privilege to its medical degrees. Sir William Gull presided last week at a meeting, held in the rooms of the Medical Society of London, convened to found a scholarship as a memorial to the late Miss Helen Prideaux, a distinguished medical graduate of the University. Miss Prideaux, after obtaining the M.B. degree with high honors, died from diphtheria contracted in hospital practice, on the eve of presenting herself for the M.D. examination, in December last. Sir William Gull confessed that he had opposed the admission of women to medical studies, but was now in favor of it. Such an opinion, though shared by many, is, however, by no means universal among medical men. One distinguished graduate in medicine, of the University—a well-known physician attached to one of the largest and oldest of the metropolitan hospitals—has ceased to use the title of M.D. since women have been allowed to enter the University, and even omits it from the Medical Directory. About ten years ago, when the question was being discussed, an eminent London physician, who had graduated at the University with distinction many years before, announced publicly that were the portals of the University opened to women, he, for his part, would seek a degree elsewhere. The promise, however, remains as yet unfulfilled.

Among recent deaths is one of a surgeon of some note—Mr. J. C. Wordsworth. Mr. Wordsworth was formerly Assistant Surgeon to the London Hospital, and Demonstrator of Anatomy in the Medical College. When the Crimean War broke out he went out to the seat of war as a surgeon. He did not go for a mere surgical picnic, as has been done several times of late years by hospital surgeons when any little war breaks out, but resigned his appointment and remained at the Crimea until the end of the campaign. He was appointed a surgeon on the army medical staff, and had charge for a time of the British Hospital at Smyrna. On his return to London he devoted himself to ophthalmic surgery, in which he attained no inconsiderable practice and repute. Mr. Wordsworth was quiet, unassuming, and genial, and much liked by his immediate associates. I believe he was no relation to the poet Wordsworth.

OUR PARIS LETTER.

(From our Special Correspondent.)

DEATH OF DRS. MACCARTHY AND WILLIAM E. JOHNSTON.

PARIS, February [illegible], 1886.

IN the space of four days the English and American colonies of Paris have each lost one of their oldest and most eminent physicians by the death of Dr. MacCarthy and that of Dr. William E. Johnston. Dr. MacCarthy died on Wednesday the 10th inst., in the seventieth year of his age. He was a native of Ireland, but came over to Paris, at an early age, with his father, who became professor of English to Louis Philippe's family. Dr. MacCarthy prosecuted his medical studies in Paris, and took his degreee in 1844. He acquired a very good practice, not only among the English residents in Paris, but also among the Americans and French, by whom his loss will be very much felt.

By the death of Dr. Johnston, the well-known American physician, the American colony in Paris has sustained a great loss. He had been more or less an invalid for some time, and the particular cause of his sufferings was somewhat obscure until about three years ago gastric symptoms manifested themselves, which seemed to remove all doubt as to the nature of his malady, though to the last he himself would not concur with the diagnosis pronounced by other physicians. Dr. Johnston was a "Southerner," and it was after the "struggle" that he came over to Europe as a newspaper correspondent, in which capacity he distinguished himself as a very clever writer and an able critic.

In 1866 he received permission to practise medicine in Paris, where he resided till the day of his death, and acquired great popularity and fame, not only as a medical practitioner, but also as a wise counsellor, and he was always consulted by the representatives of the American Government in this country upon all matters coming within the scope of his profession. He rendered valuable services to the sick and wounded during the siege of Paris and during the Commune, for which he was created Chevalier of the Legion of Honor, and later on was raised to the rank of Officer. He was also Officer of the Order of the Crown of Prussia. His funeral took place yesterday at the American Church in the Rue de Berri, the service being performed by Dr. Hough. The American Legation was officially represented. After the funeral ceremony was concluded the body was removed to the new American church, where it was laid in a vaulted chamber to await removal to the United States. The lamented physician was about sixty years of age, and he leaves a widow and an only son.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 7, to March 13, 1886.

ROBERTSON, R. L., First Lieutenant and Assistant Surgeon (Fort Ringold, Tex.). Granted leave of absence for one month. S. O. 29, Department of Texas, March 5, 1886.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending March 13, 1886.

WOODS, GEORGE W., Surgeon. Ordered to Navy Yard, Mare Island, to relieve Surgeon W. K. Scofield, April 1, 1886.

SCOFIELD, W. K., Surgeon. Detached from Navy Yard, Mare Island, and wait orders.

THE HARVEST OF DOCTORS.—The statistician will soon be busy counting the number of graduates from the various medical colleges, and the old story of an overcrowded profession will be repeated.

New Instruments.

A NEW RECTAL SYRINGE.

By W. F. MORRISON, M.D.,

IT often happens that an irritable rectum or a sensitive sphincter ani prevents the administration of a rectal enema, and compels us to prescribe medicines which we

would like to avoid. To obviate this embarrassment, an instrument has been devised, and used with great satisfaction, which relieves this valuable method of treatment of many of its objectionable features.

This instrument consists of a long rubber tube with a bulb in the centre, like the ordinary household syringe, and is operated in the same way. On the receiving end is a leaden sinker, which by its weight holds the tube in its place in the basin. A fine strainer prevents foreign bodies entering the tube. The sinker and strainer may be readily detached, leaving the end like that of the ordinary syringe.

A nickel-plated tube through which the fluid passes is attached to the other end of the tube, and is so curved and finished that it forms a convenient handle.

A quarter of an inch from the tip a soft-rubber cushion is placed, which prevents the instrument from entering the rectum. This serves also to prevent the injecting fluid from escaping or flowing out at the side. It is seen that the tip does not pass through the sphincter ani, and in this respect the syringe differs from any other in use. It has been found that when the bulb is pressed the fluid is projected forward, and enters the rectum through the sphincter ani without any constrictive action of that muscle, and no peculiar feeling of resistance or pain is noticed.

This instrument is peculiarly valuable where the parts are sensitive, or where there are piles, fissures, or other diseased conditions. As a family syringe it is superior to the one now in use, which is inserted two inches into the rectum.

It is often impossible to administer an enema to a child on account of the local irritation caused by the introduction of the syringe. But with this device an enema of tepid water may be readily administered without exciting any unpleasant sensations.

New York Post-Graduate Medical School and Hospital.—The annual dinner of this institution was held at Delmonico's, Thursday evening, March 11, 1886. The President, Dr. D. B. St. John Roosa, in opening the after-dinner speaking of the evening, referred to the fact that its foundation, in 1882, marked a new era in medical progress in New York. This Faculty were the successors of the Post-Graduate Faculty of the University. In order to carry out the plan of post-graduate instruction in a proper way, seven gentlemen composing that Faculty resigned and founded this institution, devoted solely to the requirements of practitioners in medicine. Three of these seven were in the present Faculty; one had died. The Faculty of the Post-Graduate Medical School and Hospital, being the pioneers in this branch of medical teaching, had found and surmounted the many difficulties in the way of such an institution, and had so impressed the principles of this branch of teaching upon one, at least, of the gentlemen composing the Undergraduate Faculty of the institution with which they had formerly been connected, that he allowed his name to appear as one of the directors of another school, with similar objects in view, which was founded shortly after the appearance of the announcement of the establishment of the school now celebrating the fourth, and by far the most successful, year of its existence. Over five hundred gentlemen, engaged in the active practice of their profession in all parts of this country, the West Indies, Australia, England, and Turkey, had availed themselves of the opportunities offered for post-graduate study, and the Faculty, in carrying out their original plan, had found it necessary to found a hospital in connection with the school. He congratulated the Faculty on the present prosperous condition of the institution, and commented upon the fact that it had more than seventy gentlemen composing the teaching and clinical staff. Besides some sixty members of the Faculty, several visitors were present, among whom may be mentioned Mr. Whitelaw Reid, Mr. C. C. Beaman, Mr. C. H. Kellogg, Dr. J. K. Smith, U.S.A., Dr. Abram Jacobi, President New York Academy of Medicine, Dr. Daniel Lewis, President County Medical Society, Dr. F. P. Foster, and the Rev. Dr. McArthur, all of whom took occasion to congratulate the college upon its success in ingrafting such an advance in the study of the science of medicine upon the incomplete courses pursued in the general undergraduate schools. Professor F. R. Sturgis then presented a few facts in regard to the Hospital Department, showing its growth from simply a private hospital to one where all manner of disease may be treated, and the poor receive proper special medical advice. He also referred to the foundation of the *Babies' Ward*, due to the persistent efforts of one of the instructors in diseases of children, Dr. S. J. McNutt, and of the present necessity of larger and more commodious quarters. He also referred to the possibilities that might be accomplished in these departments were the school properly endowed. Professors A. H. Smith, C. L. Dana, A. J. C. Skene, Wm. A. Hammond, and others also spoke. One hundred and fifty practitioners have already attended the sessions of the school since May, 1885, and new matriculates appear each week.

Frequency of the Use of the Forceps and the Results.—Formerly, the forceps was hardly ever resorted to until the parturient woman, worn out by the protracted sufferings she had endured, was almost moribund, and when, too, the child was probably dead, in consequence of the long-continued pressure to which it had been subjected. Thus twenty-six years ago, Dr. J. Hall Davis, in his work "On Difficult Parturition," informs us that he only found it necessary to use the forceps on seven occasions in 7,371 deliveries, or once in every 1,053 labors. In the statistical reports of the successive Masters of the Dublin Lying-in Hospital we find the most conclusive evidence of the advantage which has followed the judicious use of the forceps in later years in that institution. During the Mastership of Dr. Joseph Clarke, from 1787 to 1794, there were 10,387 deliveries in the hospital, and the forceps was only applied in fourteen of these, with six deaths. But the more easily used perforator and crotchet were resorted to in forty-nine cases, with fifteen deaths; and in his private practice, extending over forty years, Dr. Clarke only once attempted to use the forceps. In Dr. Labatt's Mastership, from 1815 to 1822, during which time 21,867 births took place in the hospital, the forceps does not appear to have been used in any instance. From 1826 to 1833, Dr. Collins used the forceps in 24 cases out of a total of 16,654, but employed the perforator in no less than 118 cases, with 24 deaths. From 1842 to 1845, Dr. Charles Johnson used the forceps in 18, the vectis in 16, and the perforator in 54 cases, in 6,702 deliveries. From 1847 to 1854, in Dr. Shekleton's Mastership, there were 13,748 deliveries in the Rotunda, and the forceps was now used in no less than 220 of these, and the perforator in 54. Dr. McClintock, who ruled the hospital from 1854 to 1861, brought the forceps into still more frequent requisition, and in his last three years of office employed it or the vectis in 76 cases, or once in every 60, in 3,700 deliveries, while the number of craniotomy cases was reduced to 5. The succeeding Master, Dr. Denham, was a still more constant advocate for the timely use of the forceps. To Dr. Johnston, the next Master, belongs the credit, however, of having brought the forceps into more frequent use than had ever previously been the case. Thus, from November, 1868, to November, 1874, in 7,027 deliveries the forceps was used in no less than 639 cases, or about once in every 11 cases, with only 39 deaths, while the proportion of craniotomy or cephalotripsy cases was reduced to 29. The foregoing statistics, as I have already said, unquestionably demonstrate that, as the forceps is used more frequently the mortality in the cases in which it is employed diminishes; and, secondly, also shows the happy effect of the free use of the forceps in lessening the proportion of craniotomy cases.—*Dr. T. M. Madden.*

Alfred Charles Post, M.D., LL.D.—Resolutions commemorative of his life and services, adopted by the New York Pathological Society, March 10, 1886:

Whereas, In the fulness of years, at the ripe age of eighty-one, our friend and long-time colleague has been taken from us in accordance with the faithful saying: "The days of our age are three score and ten; and though some men be so strong that they come to four score years, yet is then their strength but labor and sorrow: soon after it passeth away and they are gone."

Whereas, He was more than usually gifted, industrious, accurate, conscientious, pure, temperate, religious, skilled, learned in all medical, surgical, scientific, and classical lore, and gave this Society more than thirty years of his best labor. Be it

Resolved, That we will cherish his memory individually, and by preserving on our minutes and in our published transactions a truthful record of his useful and blameless life, to the end that other generations shall know him somewhat as we did.

Resolved, That while we sorrow and sympathize with his family and lineage in their great loss, we congratulate them that one so good and eminent was born among them, and was so long spared to them in health, prosperity, and honor.

Resolved, That, while we sorrow for ourselves, we rejoice that we had his wholesome example before us for such long series of years, and that part of his good repute will forever remain with us.

> "Nothing more for tears; nothing to wail
> Or beat the breast; no weakness, no contempt,
> No dispraise or blame. Nothing but was good and fair,
> And what may quiet us in a life and death so noble."

He has but gone to the beginning of peace.

Signed, John C. Peters, M.D.,
Wesley M. Carpenter, M.D.,
Royal W. Amidon, M.D

FAITH-CURES.

By JAMES HENDRIE LLOYD, A.M., M.D.,

INSTRUCTOR IN [illegible] IN THE [illegible] OF PENNSYLVANIA, PHILADELPHIA, PA.

To offer up sacrifices to the gods is human—at least the history of the human race would indicate this fact. The motive, no doubt, is usually some pressing self-interest; the circumstances have been, too often, the perversity and ignorance of self-esteem. The stern soul of Achilles, in its brutal and conceited grief, must immolate twelve captives on the pyre of Patroclus—to do what? The primitive man, we are told, never laughs; life is a burden to him, "roots are scarce," and he is in daily conflict with his great enemy—nature; but he, too, has already taken up this habit of offering sacrifice. Disease is a demon to be exorcised; death is a hideous penalty to be averted; incantations are better than drugs. In the evolution of religious sentiment these things have doubtless changed; the law of the survival of the fittest has inevitably crowded out these crude and cruel systems. Whereas there were formerly idols, there are now ideals. The material sacrifices of other days are in a measure replaced by a self-consecration; the gifts of wine and bullocks are discarded for a state of mental erythism—a so-called spiritual effect.

It must be apparent to a careful inquirer, however, that there are what the biologists call *reversions* in these modern forms of religious thought, which reversions proclaim infallibly their kinship to the older types. When Pieta proclaims that she has been cured of her neurasthenic spine by faith, *i.e.*, by a sort of ideal abandonment of self, with prayer and unreasoning confidence, to the divinity, she does not differ essentially, in her non-appreciation of the physical laws of disease, from the Egyptians who sacrificed in the temples of Canopus. The fundamental fact, in each instance, is that the devotee believes that the universal laws of nature are suspended for his or her special benefit by supernatural power. The zeal of some of these modern disciples is not unlike that of Elijah and the followers of Ahab, when they contended together to exhibit the power of prayer; and the presumption of the unfortunate priests of Baal appears greater, only because of its more tragic climax, than that of the faith-curer, who said that he furnished his house by prayer, even to the melodeon! We do not seem far removed from the classics when we read the story of the death of Dom Pedro's mother. The Empress, it seems, was devoted to a miraculous image of the Virgin, which performed cures; but the image was at last offended by being carried to the Empress when she was too ill to be carried to it, and not only allowed the imperial lady to die, but even killed off the Archbishop with cholera morbus.

A continued interest in this subject of faith-healing is perhaps excusable for several reasons. The mystery of the cases, and the astonishing results claimed, challenge the attention, and not unfrequently puzzle the understanding. They are generally so related also as to throw discredit and opprobrium upon the physicians who have happened to be in attendance upon the case. Then, again, they may lead to some astounding development in archæology, finance, or even in the dark sciences—as in the case at South Orange, N. J., where a woman, who had been a cripple for many years, was cured by faith; whereupon her husband immediately started a fund for $20,000 to enable him to recover a certain stone in the Sphynx, which is an infallible cure-all. Another reason is stated by the *Philadelphia Press*, which says that faith-cures are a good thing because, like the whipping-post in Delaware, they are cheap. But a more valid reason for interest in these cases, and the one which is the cause of this paper, is to endeavor to extricate a few of the exact facts from their perilous admixture with mysticism and fiction.

Some time in the early part of last year, the Society for Psychical Research, in Philadelphia, appointed a committee to investigate faith-cures. The writer was chairman of this committee, and in consequence has devoted more or less time to the subject. The object was intended to be entirely *psychical*, and not at all *polemic*. It was not proposed to enter into the general subject of answer to prayer, but simply to investigate these individual cases of alleged faith-cure. It was the personal belief of the writer that such investigations would lead to some interesting facts in psychology and, perhaps, psychiatry. Esquirol has said, "Generally, mental alienation is terminated by sensible crises," and it seemed a good thing to determine how far some of our remarkable cases were only these "sensible crises" occurring in a neurotic constitution. It was, of course, desirable to avoid the error of going over old ground entirely; it was well to be mindful of the hackneyed facts of the stock text-books and of the elaborated work of Tuke.[1] With the aforesaid object in view, the investigation was pushed with some vigor, and while it did not disclose the wealth of facts in matters psychical which had been hoped, it did bring to light a variety of interesting and even remarkable truths. A verbal report to the Society closed the committee's labors, and the chairman has felt free to record some of his observations.

First. The method pursued and difficulties met with Two series of questions were proposed, as follows:

A. (To Faith-curer): I. What diseases have you cured, especially *fevers?* (Typhoid, small-pox, scarlatina, measles, and graver forms of malaria?) *Nervous diseases?* (Paralysis, what form? Apoplexy, chorea, epilepsy?) *Tumors* (cancer and ovarian?) *Wounds* and *fractures?*

II. *Method?* (By faith alone, or were surgical or therapeutic means used in any cases?)

III. Patients' names and addresses, which would not be printed if so requested.

B. (To Patient): I. *History of case?* Cause, course, symptoms, duration, and treatment, with results? Condition just preceding cure? (Had patient been improving, growing worse, or stationary?)

II. *The cure?* Circumstances which induced application? Condition of mind at first—belief or doubt? Length of time to effect cure?

III. *Recent history.* Thoroughness of cure? Interval since cure? Relapses—how many? Is improvement more marked than that obtained by medical treatment?

The above questions were used for those who lived at a distance. In all cases where practicable a personal examination was requested; if such examination were not practicable the aid of the family doctor was solicited. It soon became apparent, in the search for cases, that the city of Philadelphia had not enjoyed the therapeutic benefits of faith in that superabundance which one might

[1] Influence of the Mind upon the Body, by H. Hack Tuke.

have supposed, and which seems to have been the fortune of more distant localities. What there is in the latitude and longitude of the Quaker City that predisposes its constitution to resist this mild remedy must be left for sanitarians to determine. It is certain, however, that, although the search was industrious, and even announced in the public press, and application made to the most distinguished practitioners of the cure (as shall be seen), there were only negative results obtained, which are nevertheless of value.

It did not seem difficult to obtain the addresses of cases in Boston, New York, and the West, but most of the letters written to them remain unanswered to this day, while some of the answers which were received await our more detailed criticism. Captain R. Kelso Carter, quite a distinguished supporter of the doctrine, and who has been announced himself as cured of "fatal heart disease," very kindly wrote a letter containing the following extracts: "Doubtless some healed ones would innocently submit to a medical examination. I would not, believing it to be dishonoring to my great Physician. I give my testimony—and I say Jesus cured me. I do not propose to submit to tests, to endorse God's notes of promise by the signature of men." The reports written by the patients themselves proved to be always so inexact and loose-jointed, that it was quite impossible often to make out the semblance of a diagnosis. Their likeness, indeed, to the cases advertised by the patent medicine men was very striking. They often, too, had a little of the tone of a modern clergyman's endorsement of soap.[1]

Dr. Charles Cullis, of Boston, is no doubt one of the most prominent practitioners of this newest school. The writer addressed a letter to him and received a very brief and unsympathetic reply, in which he said that he had cured all the diseases mentioned "except perhaps *small-pox*," which had never been presented to him. The letter contained the following curious passage: "In regard to wounds and fractures, I should employ a surgical aid and trust the Lord to perform the healing." This seems to be a specimen of tergiversation; and moreover, it will presently appear that herein Dr. Cullis is not up to the traditions of his profession. Shortly after this letter an article in the *Century Magazine*[2] contained a very able criticism from the genuine orthodox standpoint, and taxed Dr. Cullis and his friends with lack of candor for not publishing lists, as our hospitals do, of the "dead" and "uncured" as well as "cured." Another letter was then addressed to Dr. Cullis soliciting such a list, but the letter has never been answered. If the doctor desires at some future day to make up such a list, he is at liberty to draw examples from this paper.

In October last a Convention of Faith-curites was held in Philadelphia. A letter was addressed to this body, which included many illustrious delegates, inviting their co-operation in this good work for humanity and the cause of truth. Cases were especially requested for examination. As no notice was taken of the letter a delegate was asked subsequently for the reason. He replied that the convention had tabled the letter because it did not consider such investigation to be part of its business. Rev. A. B. Simpson writes: "I should as soon expose the sanctity of my home life to the public eye, as the sacred work of God in human bodies . . . to scientific criticism;" but he appears to forget that the "sanctity of his home" is a purely personal matter to himself, whereas the healing of human bodies is of very near interest to every individual who has one; and that the subject is open to scientific criticism, and will stand or fall by it *alone*. Rev. John E. Cookman, who is an enthusiast, writes, "I do not say it in any captious or hypercritical way, but as an honest and fair criticism, . . . that a society for psychical research might have been formed in Jerusalem, Judea, Samaria, or Galilee, in the days of our Divine Lord, to investigate the cases of healing wrought by Him, with as much pertinency as your present society." The various possible applications of this remarkable paragraph must be made by each reader for himself. Mr. Cookman was himself healed by faith of "nervous prostration;" and, with great latitudinarianism, in spite of the above paragraph, sent several addresses of patients.

Second. The results. It was not possible to give some cases thorough examination because of the delicacy of the subject. This was true of obstetrical cases, in some of which there have probably been remarkable and speedy "cures;" in fact someone has spoken of the whole subject as the "*miraculum naturæ*." One physician reported a case, which happened at a distance, of a woman who shut herself in her room when her pains came upon her, and relied entirely upon divine care in her delivery, but who unfortunately took to flooding and would have lost her life, had not a physician been called to her side. There may be other cases. But it is not remarkable that some of these ladies succeed in their rash enterprise, when we consider what a large percentage of women are delivered successfully every year, with no one but ignorant midwives in attendance.

The following case came directly under the writer's notice. An infant, aged a few months, had a very bad congenital vascular nævus of the upper lip, which was very disfiguring and caused the family much concern. Dr. Cullis came this way, and held meetings in a church edifice which was converted into a free dispensary for the treatment of all manners of disease by faith. Prayers were solicited for this child, and offered for it, but as every medical man would expect, the nævus got no better, but only worse. This was in every sense a crucial test. The failure could not have been due to a "lack of faith" (which is the favorite argument), because, as the infant was too young to bear this reproach, the faith of the friends would suffice, and even if that were lacking there was the vicarious faith of Dr. Cullis. The writer had the opportunity afterward of seeing Professor Agnew excise this growth and effect a *scientific* cure.

The following case is brought forward as a specimen of the rambling pathology, which renders a scientific diagnosis very hazardous. M. E. D—— has published her own case in a tract, and has further described it in a letter which was revised by her physician, who is a female doctor. She "inherited a weak back from her mother, who had spinal disease." She fell down-stairs, which added to her inheritance. Then she had "malarial fever;" then came "seven attacks of diphtheria," which went "down the passages and into the stomach," and caused a diphtheritic ulceration of the stomach "which continued for four years." Twice in that time there were abscesses (location not stated) "which discharged a pint from the diphtheria." "Also I had paralysis." Then came a hyperæsthetic spine, and prospects of being "strapped to the bed," because "her limb was in continual motion." Then she had trance-like spells, with closed eyes, but perfect consciousness. Then the account becomes grewsome in the extreme. "I well remember the first attack of the kind. My doctor was away, and my father was away from home also; my mother was alone; for hours she waited, hesitating whether to send for the undertaker or to await the return of my father. I heard all that was said, and was in an agony of fear lest I should be put into an ice-casket alive. At last my mother discovered a slight motion of the eyes, and she continued working with me until I could speak." Then came lateral curvature of the spine; then the opium-habit; then contracture of leg-muscles; then anæsthesia of the skin; then the sum total of the pathology is given as "congestion of the spinal cord at the seat of the lumbar plexus." One is reminded of the poor ghost in Dante:[3]

> Thus one perhaps
> Hath been by force of palsy clean transposed,
> But I never saw it not believe it so

[2] Faith-cure, by A. J. Gordon, December, 1885.

A detailed criticism of such a case is, of course, not possible, but medical men will see at a glance that *Hysteria* is written in big letters all over it. Another, and parallel, case is that of Miss Carrie Judd, of Buffalo, as published by herself. It is probable that no layman, or woman, has ever written a more exact account of chronic hysterical invalidism, than has Miss Judd in her description of her own case.[1] She is to be complimented on the easy professional swing of her pen—up to that place where she said that her disease "had grown into blood consumption," which term savors too much of the patent-medicine puff. The patient was paralyzed, bed-ridden, hypersensitive and tyrannical to the last degree—as shown by the "silent house," as she calls her home, from which it was scarcely possible to bury her grandmother, because the patient was "so low." It is quite unnecessary to go into the details of her case; medical literature abounds in such, and in their not unfrequently sudden cure. The writer calls to mind at this moment cases in the writings of Laycock, Skey, Mitchell, and Emmet, which are more striking than that of Miss Judd.

It has always been the reproach of the faith-curers that their successes are with the mere *functional* disorders, and that they have never produced an effect upon serious *organic* affections. But they have recently had several champions come to the front with quite a formidable array of cases of cancers, fractures, and other severe ills. For instance, the Rev. R. L. Stanton has written a pamphlet of almost one hundred pages[2]—a very trenchant work and well calculated to win a certain class of converts and propagate error; in which he parades the most startling cures of tumors, cancers, and broken bones. But if all of his cases are not more authentic than the one quoted below, let us hope that his book will be expurgated before it reaches another edition. The case referred to is that of a little son of Dr. Reed, a physician of Philadelphia, who fell and broke both the bones of his forearm. The account says that the patient insisted the following morning upon having the dressings removed, because Jesus had made it well; that the child was so confident and persistent that on the third day the surgeon, who was the boy's uncle, did remove the splints and exclaimed, "It is well, absolutely well;" and "hastened to the door for air to keep from fainting." This case has been so widely circulated, and in such good faith, that it was very desirable to know more about it. It so happens that the patient is now grown to manhood, and is himself a graduate in medicine from the University of Pennsylvania. A letter was addressed to him and the following very interesting and amusing reply was received:

"DEAR SIR: The case you cite, when robbed of all its sensational surroundings, is as follows:

"The child was a spoiled youngster who would have his own way, and when he had a "*green stick*" fracture of the forearm, after having had it bandaged for several days, concluded he would much prefer going *without* a splint. . . .

"To please the spoiled child the splint was removed and the arm carefully adjusted in a sling. As a matter of course, the bone soon united, as is customary in children, and being only partially broken, of course all the sooner. This is the miracle!

"Some nurse, or crank, or religious enthusiast, ignorant of matters physiological and histological, evidently started the story, and unfortunately my name—for I am the party—is being circulated in circles of faith-curites and is given the sort of notoriety I do not crave.

"I have been pestered with letters on the subject from ministers and members of the fraternity who seek to rob us of our patients, but have consigned all such letters to my waste-basket. . . . I take pleasure in giving you these few notes, trusting they will satisfy your mind in regard to this example of faith-cure.

"Very respectfully yours,

"CARL H. REED."

The Rev. Mr. Stanton ought to make a dog-ear on this leaf for future reference, because this letter of Dr. Reed's spoils the most interesting story of supernatural healing of a fracture that has appeared since the day when Diomedes threw a great stone at Æneas and caused a compound fracture of the femur, which is supposed to have been cured by Venus, the divine mother of the injured hero. This case is reported by Homer, and has probably not been investigated.

During the past autumn the writer's attention was several times called to a home for sick and injured in Philadelphia, where the treatment, support, and everything was by faith. It was kept by a medical graduate of Harvard, who is an ex-member of Congress, and was announced to contain a room in which were piled up the crutches and other surgical gear which patients had cast off after their miraculous deliverance from disease. The impression conveyed by reports was that troops of patients were daily cured, and that old cast-off canes were as plentiful as at the once notorious shrine of Knock. The writer visited this house, and was received graciously on two occasions; he was shown all over the establishment, and noted that no patients were there at that time. Inquiry was made for the room of discarded crutches, whereupon the proprietor smiled, as though he saw the joke, and said that that story had been somewhat exaggerated—in fact, he had but *one pair* of crutches, and that pair was from a patient who probably had never needed them! He then went on to describe the case. The patient was a woman, who had been diagnosed at a homœopathic hospital to have lateral curvature of the spine, but for his part he was not certain about it, because he doubted the homœopathic ability to make a correct diagnosis. When asked if he had not made his own diagnosis, he said he had not time to do that in his peculiar work, that he could not trouble himself about diagnoses, but still he thought he detected the curvature under the patient's dress; and as he prayed he felt it suddenly straighten. When asked if the patient was entirely cured he said, "No, she still has the curvature!" The address of this patient was withheld.

A lady in New England took great pains to report a case, and did it so well, that an important deduction can be drawn from it. It was a case of hip-joint disease, or bone disease, with large discharging sinuses, in which rubber drainage-tubes had been kept, as is customary, for a long period. The patient, a child with firm faith, attended a "novena" (a sort of nine days' devotion), at a Roman Catholic church, and at the same time threw aside tubes and treatment. In about *two months* the sores had healed, but the leg remained stiff. The obvious criticism of this case is the fact that a miracle would not have taken two months, and that the cure was not much to boast of as divine, if the leg remained stiff. The physician to the case is reported as attributing the cure, very wisely, to a fortuitous removal of the tubes at just the right time.

Miss Louisa M. Alcott writes of the *mind-cure* (which is a kindred branch with faith-cure), that although it failed in her case, she is convinced there is a "great truth" in it, but she does not say what the great truth is. As for her, "homœopathy has worked more miracles than the mind-cure." This will probably confirm some of us in the suspicion that homœopathy is another branch of psycho-therapeutics.

The conclusion of the whole matter brings us to one more point. The mystical language used by these people is often responsible for many of their errors. This language can often be neither parsed nor translated. Said one good woman to the writer, "You cannot understand these things because they are spiritual, and you do not

[1] How I Entered Into Rest. By Carrie F. Judd.
[2] Healing through Faith, etc.

believe;" as though the alleged healing of the cancer in the Rev. Mahan's wife was not materialistic enough to be looked after. A clergyman wrote that he hoped the "ethical nature of disease" (whatever that is) would be explored. Some few of the advanced guard have forged ahead to the only one logical conclusion, and, with Stockmayer, proclaim that with one great combined, cumulative exercise of faith by the Christian Church death will be eventually abolished from the world.

Far be it from the writer to ignore the just claims of religious emotion upon the mind of man; but it is sometimes comfort to reflect, with Epicurus of old, that those are not undevout who deny the gods of the many, but those who attribute to the gods the opinions of the many

ABORTIVE TREATMENT OF GONORRHŒA.

By S. O. VANDER POEL, Jr., M.D.

VISITING PHYSICIAN TO CHARITY HOSPITAL, NEW YORK.

For about three years almost daily systematic observations as to the local effect of various drugs upon the urethral discharge in gonorrhœa have been made at the Dispensary of Roosevelt Hospital under the supervision of Dr. William S. Halsted.

Starting with the premise that gonorrhœa proper is due to a specific germ, Neisser's gonococcus[1]—and there can at present be no reasonable doubt as to its existence or specific character, since Neisser's claims have been confirmed by so many careful observers (Aufrecht,[2] Leistikow,[3] Krause,[4] Wolff,[5] Eschbaum,[6] Bokai,[7] Bockhart,[8] and Podres[9])—and recognizing that in order to cure the discharge its cause must be eliminated, it was sought to find a substance which would destroy the micrococcus and at the same time not injure the urethral mucous membrane. It is my purpose to present a method, believed to be abortive, first considering the various steps that led to it, and from which it was evolved. In all the cases that form the basis of these experiments the microscope was used in the examination of the discharge, both for purpose of diagnosis and to note the effect, if any, the measure used had in destroying the micrococcus. All previous claims to abortive treatment in which this precaution was not taken can scarcely be accepted as well-authenticated facts when we consider the danger of confounding cases of specific urethritis, due to the presence of a germ, with the non-specific variety occasioned by exposure to leucorrhœal discharge, to the secretion from an endocervicitis, to menstrual fluid, acrid vaginal discharges, traumatic influences, etc., in none of which is the gonococcus found.

Hot-water irrigation, strongly advocated by Vajda (Schmidt's *Jahrbücher*, 1880, p. 166), was among the first substances used. It acts as a sedative to the inflamed mucous membrane, and is consequently grateful and soothing to the patient; its effect on the gonococci is to apparently diminish them in number, provided the irrigation is performed sufficiently frequent to keep the urethra free from discharge, its action being simply mechanical, that is to say, that as fast as the germs are formed in the mucous membrane and find their way into the urethra they are washed out by the irrigation, but as the hot water produces in the mucous membrane a soil in which they propagate rapidly, and exerts no action in destroying them, they are found as numerous as before just so soon as the irrigation is discontinued. In order to test its efficacy in cleansing the urethra I have had a patient irrigate at a single sitting with eight quarts of hot water. Microscopic examination of the urine first passed after the irrigation disclosed pus-cells in large quantities, demonstrating that it is practically impossible by means of bland fluids to free the canal.

A somewhat extensive use of the short catheter as a means of introducing fluids into the urethra in gonorrhœa, first suggested by I. P. Prince (*Medical Times and Gazette*, October, 1875), has led us to abandon it, in consequence of the pain occasioned upon introduction. The testimony of patients upon whom both the catheter and the blunt nozzle have been used is unquestionably in favor of the latter.

A saturated solution of boric acid in cold water is perhaps one of the most soothing applications that can be employed in urethritis, far exceeding hot water in allaying the irritation and burning. But the same objections are applicable to it as to hot water, namely, that its destructive action on the gonococcus is almost nil, as after its continued use for weeks, they are still to be found in the discharge. It would seem that the ordinary complications of gonorrhœa, cystitis and epididymitis, are more likely to occur during the use of non- or feebly-antiseptic substances, such as hot water or boric acid; the micrococci being carried into the bladder, there to kindle inflammation, or being absorbed by the lymphatics which accompany the vas deferens travel through them to reach the epididymis.

It was believed that if iodoform could be brought into intimate contact with the inflamed mucous membrane, in consequence of its anæsthetic properties and its controlling influence in governing the migration of leucocytes, it would prove serviceable. Watson Cheyne, in the *British Medical Journal* for July, 1880, claimed for it a specific abortive action when introduced in the form of soluble bougies with eucalyptus oil, but he has since retracted his assertion. Two years since it was used by Dr. Halsted in the form of an ointment made up with cold cream in the proportion of 1 to 6, or 1 to 8, and injected through a blunt glass nozzle from compressible metallic tubes similar to those in which artists' pigments are sold. By this means half an ounce of the ointment could be introduced without pain or discomfort, which was the principal objection to the soluble bougies of Watson Cheyne. It was found most serviceable in quieting frequent micturition, and would also allay the annoying itching or tickling, so frequently experienced in the latter stages of gonorrhœa. But in my hands it did not materially diminish the amount of discharge, or shorten the duration of the disease. Among the other drugs that were successively used in a series of cases, and in most instances with indifferent success, may be mentioned acetate and sulphate of zinc, sulphate of lead, carbolic acid, salicylic acid, peroxide of hydrogen,[1] tannic acid, nitrate of silver, and bichloride of mercury.

The latter, when used as it was at first, in the strength of 1 to 8,000 or 1 to 10,000, a single injection with the ordinary urethral syringe being given daily, was found to excite so much inflammatory reaction that it was necessary to supplement it with irrigations of boric acid. Even with this precaution it was impossible to continue it more than two or three days, for if persevered with it occasioned painful and frequent micturition with bloody discharge, and in one instance temporary retention. Notwithstanding these disagreeable features, under its use the discharge rapidly diminished, the gonococcus could no longer be found, but would reappear after the lapse of some days. A substitution of a milder solution, 1 to 20,000, when introduced in the same manner, was likewise too irritating to be continued long enough to kill all the germs. Podres has had a similar experience with the bichloride when used in this strength, 1 to 20,000, but in

[1] Centralblatt f. d. Med. Wissen., 1882, No. 51.

[illegible] Wochenschr., Nr. 13, 1883.

[7] Bokai: Vierteljahresschr. f. Derm. u. Syph., 1881, Heft 1.

[illegible] Vierteljahresschr. f. Derm. u. Syph., 1885, Heft 3 und 4.

a few instances—where the urethra was unusually tolerant and he could repeat the injection every two hours during the day—claimed to have aborted the disease in five days. His present method is to begin with 1 to 20,000 and continue just so long as the urethra will tolerate it, using for the remainder of the course the ordinary astringent solutions. With this plan the average time taken to effect a cure is three weeks.

As a result of the experiments thus far it was manifest that the bichloride, in spite of the irritation caused, seemed best to control the disease, and the necessity of employing an agent that would kill bacteria was evident. The investigations of Koch upon the culture and pathogenesis of gonococci, from which most of the antiseptic forms of treatment are deduced, would show that while the bichloride of mercury is by far the most active agent in destroying the germ in artificial cultures, it was necessary to use it in comparatively strong solutions (1 to 20,000), too strong in fact to be continuously borne by the urethra.

The experiment of Bockhart indicates that artificial cultures of gonococci grown upon blood-serum are more virulent than those which ordinarily develop in mucous membranes. He inoculated the urethra of a paralytic dement with an artificial culture of gonococci four removed, and established a gonorrhœa of such severity that the subject died in ten days. The mucous membrane and lymph-channels of the entire genito-urinary tract were infiltrated with the micro-organisms, while a metastatic abscess of the kidney, and a necrotic spot in the bladder were filled with the germs. It is probable, then, that the sterilized blood-serum upon which the germs were cultivated formed a better propagating soil, giving them greater life, power, and resistance to germicides than is furnished by the urethra. The fact that gonococci propagate in the mucous membrane, from which they gradually find their way into the urethra, and are not to any extent developed in the canal itself, explains why they are not all destroyed by the stronger solutions. Those that the bichloride comes in contact with in the urethra are killed, but as it is impossible, in consequence of its irritating properties, to continue it more than a few days, the ones that are forming beneath the epithelial layer of the mucous membrane are not reached, and as they migrate into the urethra, re-establish the discharge. For experience shows when using these stronger solutions the gonococci disappear, and the amount of discharge materially diminishes just so long as they can be continued, only, however, to reappear when we are obliged to discontinue them.

These considerations suggested the idea of irrigating the urethra with large quantities—two to three quarts—at each sitting of a weak solution of bichloride of mercury (1 to 40,000) and repeating the procedure three or four times a day. The modus operandi is simple, and when once explained and demonstrated to a patient can be effectively carried out by him at home. These irrigations are best accomplished by hydrostatic pressure, the most convenient form being the ordinary fountain syringe, with a blunt glass nozzle of sufficient size to occlude the meatus. By suspending the syringe at a proper height a force is produced which will comfortably distend the urethra, avoiding a pressure which would carry the injected material into the bladder, although experience shows that its presence there is productive of no harm, since the germs are previously destroyed by the antiseptic. About four feet above the pelvis of a patient as he sits upon the edge of a chair has been found most serviceable. The stream is then permitted to flow continuously, the nozzle being held in the meatus, so that the fluid may permeate the entire length of the canal, and at the same time allow of its escape by the side of the nozzle. The sensations of the patient are the best guide for determining the depth to which the fluid permeates. When it reaches the neighborhood of the prostate, it produces a sensation similar to that experienced in urinating. With a little experience they readily acquire the technique necessary to carry the fluid well back in the canal, and at the same time permit of its regurgitation through the meatus by the side of the nozzle. Great differences will be found in urethræ as to their susceptibility to the bichloride solutions, as frequently cases are seen which cannot continuously use irrigations as weak as 1 to 40,000, and again there are those who can bear it as strong as 1 to 20,000 without inducing an irritation sufficient to cause its discontinuance. It would seem, then, a safe rule to begin with 1 to 40,000, and if it is well borne, producing but little irritation with a slight burning after irrigation, and no frequency in micturition, it may be continued, but if these symptoms are intensified, and should be accompanied by a blood-tinged discharge, it is best either to discontinue it for a day or two, or substitute a weaker solution, 1 to 60,000.

This treatment has now been employed in eight cases, by four different observers, who have, without exception, succeeded in aborting the disease in from eight to fourteen days. The diagnosis was verified by microscopic examination, gonococci being found in each instance. Subsequently the discharge was examined daily, with the result of showing the disappearance of gonococci on the third to sixth day, the discharge itself daily diminishing, to cease entirely on from the fifth to tenth day. After the microscope has shown the germs to be no longer present in the discharge, it is still necessary—in order to reach those germs which are in the lymph-spaces of the mucous membrane, to continue the irrigations for three days, when, if the discharge has not stopped, it is advisable to use some mild astringent with the ordinary urethral syringe. A solution of nitrate of silver, gr. ¼ to ʒ j., will be found most serviceable in checking this discharge, which is caused by the irritating action of the bichloride.

The entire freedom of the patients thus far treated from the ordinary annoyances, burning and scalding, with frequent micturition, is worthy of note. In fact, so slight discomfort did they experience, that there was little to remind them of their trouble, save the necessity of frequent irrigation. Although the number of cases in which this plan has been followed is small, the fact that four different observers have succeeded in aborting the disease in all the cases in which it was tried, and have not been able to do so by any other method, would tend to give it additional weight.

The complications—epididymitis, cystitis, and rheumatism—that not infrequently arise during the course of a blennorrhœa, are usually the most distressing part of the ailment, prolonging its duration and intensifying the suffering. Epididymitis, perhaps the most frequent, can often be anticipated by recognising the premonitory pain and soreness complained of along the course of the vas deferens. If the painful area be thoroughly but lightly touched with the thermo-cautery the pain will cease, and perhaps the progress of the inflammation along the course of the lymphatics will be arrested. When the epididymis is involved, applications of the cautery will cause the pain immediately to subside. It is necessary, however, that the point should not be heated beyond a dull red, and that the testicle be quickly and lightly touched, producing a general blush over the surface, such as is seen after the application of a sinapism. In several instances where this has apparently failed to give relief a very small hydrocele was found, and when this was emptied with a hypodermic syringe, the pain would disappear. After the use of the cautery a thick poultice of iodoform ointment, 1 to 6, will materially shorten the course of the inflammation.

Rheumatism occurs too frequently during the course of gonorrhœa to be considered a mere coincidence, even if we did not have the incontrovertible fact of the presence of gonococci in the fluids of the inflamed joints. Generally these rheumatic complications are among the most obstinate we have to deal with during the course of a

blennorrhœa, it frequently taking months to effect a cure. The bichloride would likewise here seem to play an effective *rôle*. If, for example, it be the knee or other large joint that is involved, and the capsule is distended from intra-articular accumulations, it should be aspirated with antiseptic precautions, and a solution of 1 to 20,000 bichloride of mercury thrown into the joint-cavity. This was recently done in a case at Bellevue Hospital, where a man had been confined to bed for some days with gonorrhœal effusion in the knee-joint, over which morphine had but little effect in controlling the pain. He was immediately relieved by the operation and the following day was up and about the ward. When the inflammation is diffused in the fibrous tissues surrounding a joint, as frequently occurs about the wrist or ankle, a hypodermic injection of 1 to 10,000 down to the bone will yield at times most satisfactory results, a preliminary injection of cocaine being given. A girl of five years of age was brought to the dispensary with an inflamed shoulder-joint. It being an invariable rule to examine the urethræ of cases with acute articular trouble, gonorrhœa was found, the diagnosis being verified by the microscope. In this case deep injections, down to the bone, of bichloride were made rapidly, relieving the symptoms, for which she had been unsuccessfully treated outside by the ordinary anti-rheumatics. For cystitis the ordinary irrigations with mild antiseptics have proved most serviceable, boric acid being preferred. Since we began to use bichloride, even when experimenting with the strong solutions 1 to 8,000 or 1 to 10,000, none of these complications have been met with.

Cases of so-called gleet, for which the passage of a sound is recommended, are frequently seen to grow worse after an instrument has been introduced, while in others decided benefit follows its use. The explanation of this apparent contradiction would seem to rest in the fact that in the first instance gonococci are present in the secretion, and as the sound passes it spreads the infectious material along the canal, developing new foci of disease, and if by chance the tip of the sound carry any of the discharge into the bladder a cystitis may be established.[1] When benefit is derived from the sound the discharge is usually prostatic, contains no gonococci, and is attended by a swollen and slightly tender prostate. It can, therefore, we think, safely be asserted that the passage of a sound does no good, and frequently is productive of much harm, just so long as the micro-organisms are demonstrable in the discharge.

In cases of gleet the character of the discharge and the presence or absence of gonococci will frequently give valuable hints in treatment. If the discharge assumes a fibro-plastic character, adheres tenaciously to the urethral wall, forms a coating on the mucous membrane, and contains gonococci, it will resist most obstinately the ordinary astringent injections, although the amount of discharge that escapes through the meatus is small. If such a variety be first thoroughly irrigated with some warm solution (preferably boric acid), in order to dissolve off the tenacious secretion, it can be readily cured by bichloride irrigations.

Then again, other cases of long-standing discharge will present themselves, who tell you that they see but little discharge during the day, but sometimes after urination and in the morning a drop or two of thick pus will present itself at the meatus. Endoscopic examination will often show the fossa navicularis or some of the sinuses in its neighborhood to be the seat of trouble. If this be found it is advisable to manipulate the urethra externally at this point, when generally a drop of thick pus can be made to exude, which leaves a surface upon which the bichloride can be effectively used. A combination of both these varieties of gleet may exist in the same case, when it is necessary to recognize the seat of the trouble and character of the discharge before a cure can be effected.

DIPHTHERIA AND ITS TREATMENT.

By SAMUEL W. SMITH, M.D.,

NEW YORK.

Mortality reports establish the fact that diphtheria ranks among the most fatal diseases known to medical science, as is shown by the following statistics kindly furnished me by Dr. John T. Nagle, Deputy Register of Records in the Health Department of New York City:

Year.	Cases reported.	Deaths.	Per cent.
1880	3,307	1,390	42.032
1881	5,272	2,249	42.659
1882	3,507	1,525	43.484
1883	2,906	1,009	34.377
1884	2,201	1,090	49.477

An average of 42.405 per cent.

From January 1, 1885, to September 1, 1885, the statistics given me by months are as follows:

January reported 221 cases, with 101 deaths, or 45.701 per cent.; February reported 259 cases, 110 deaths, or 42.471 per cent.; March reported 229 cases, 118 deaths, or 51.528 per cent.; April reported 236 cases, 103 deaths, or 43.644 per cent.; May reported 287 cases, 116 deaths, or 40 per cent.; June reported 253 cases, 111 deaths, or 43.873 per cent.; July reported 202 cases, 98 deaths, or 48.514 per cent.; August reported 133 cases, 71 deaths, or 53.383 per cent.; September reported 149 cases, 83 deaths, or 55.711 per cent., or an average of 47.209 per cent.

Hence this disease becomes a theme of corresponding interest to every conscientious practitioner of medicine, and when one hears a physician say (as was said to the writer not long since in consultation) that he had treated scores of cases of diphtheria every year, amounting to several hundred, without a single fatal result, one is warranted in doubting the reliability of the man and justified in regarding his "facts as fictions."

Divers theories respecting the character and treatment of diphtheria are held by equally respectable authorities, which I shall not attempt to discuss in this paper, but state such facts as appeared in the study of the following thirty cases, treated by me, as well and concisely as I can.

I came to have an extended experience in dealing with this disease, and devoted especial study to it, some four years since, in company with Dr. C. E. Billington, whose most excellent paper, read before the Academy of Medicine a short time previous, upon "Diphtheria and its Treatment," I had perused with much interest. I determined at the first opportunity to test its efficacy. Dr. Billington had several cases of diphtheria which we jointly treated, and in which we religiously followed the plan of treatment previously set forth in his paper. The result was flattering, there being two deaths in ten cases treated by us, and both had become laryngeal at the time of our first visit.

This plan of treatment, which I have adopted since it became known to me in every case I have been called upon to treat, and which I gladly make so prominent in this paper, consists in the most thorough medication of the parts affected with a solution composed of one teaspoonful of common salt to a pint of lukewarm water, to be forced with a common ear-syringe into the nostrils and throat of the patient every two hours. I added to this salt-water solution one to two drachms soda biborate, a solution to be used with a hand atomizer every half hour, composed of aqua calcis, oz. iv.; acid. carbol., gtt. x.; and the employment internally of tr. ferri chloridi with glycerine, alternated every half hour with potass. chloras.

I consider the soda biborate one of the best and least irritating of antiseptic solutions, especially to the nasal mucous membrane. The sodium chloride certainly promotes osmotic action; and when the diphtheritic membrane is not sufficiently loosened to be washed away by

the stream of antiseptic solution from the syringe, this action facilitates the contact of the solution with the decomposing putrescent material underlying the diphtheritic deposit.

The iron, I believe, acts as nearly as a specific in this disease as it does in all forms of erysipelas, and in small doses, frequently repeated, is of great value for its local effect, and the glycerine seems to have a sustaining power of great value.

The large doses of tr. ferri chloridi recommended by some to children from three to five years of age—half a drachm to a drachm every hour or two—I think injudicious, unwise, and unscientific, and for this reason, if given in excess of amount entering into the circulation it must necessarily act as a local irritant to the digestive tract. It is a recognized fact that one of the great dangers to the life of the diphtheritic patient, whether the local affection be primarily or secondary to the disease, is the septic poisoning by the absorption of the decomposing putrescent material as the result of the local necrotic process. My observation in the treatment of the disease has proved to my mind, beyond a doubt, that this local septic poisoning is the only danger to the life of the patient, except in those cases where the disease becomes laryngeal, or extends to the trachea and bronchi. Hence, I would say to those who would call upon the skin, kidneys, and intestines with their shot-gun style of administering drugs for the purpose of eliminating the poison of diphtheria, that to my mind it would be as reasonable to suppose that the septic poisoning from a decomposing retained placenta could as easily be eliminated by the use of drugs in the stomach, or a dirty-faced boy made clean by a dose of castor-oil.

FORMULÆ.

I.—℞. Sodium chlorid..... ℥ j.
Sodæ biborat..... ʒ j.–ʒ ij.
Aquæ fervens..... Oj.

M. et Sig.—Use with a syringe into the nose and throat every two hours, lukewarm.

II.—℞. Acid. carbol..... gtt. x.
Aquæ calcis..... ℥ iv.

M. et Sig.—Use with a hand atomizer in the nose and throat every half hour.

III.—℞. Tr. ferri chloridi..... ʒ j.
Glycerine..... ʒ j.
Aquæ..... ʒ jss.

M. et Sig.—Dose: a teaspoonful every hour.

IV.—℞. Potass. chlorat..... ʒ ss.–ʒ ij.
Glycerine..... ʒ ss.
Aquæ calcis..... ʒ ijss.

M. et Sig.—Dose: a teaspoonful every hour, alternated with No. III.

When an unirritating astringent is deemed advisable, I add to No. I. formula tr. kino, ʒ ss.–ʒ j.

Since treating the following cases, I have used with the atomizer, instead of No. II. formula, the following formula, and am well pleased with it:

℞. Listerine..... ʒ vj.
Glycerine..... ʒ iij.
Aquæ rosæ.....q. s. ft. ℥ iv.

M. et Sig.—Use ¼ with the hand atomizer instead of No. II.

I adopted this plan of treatment in the very spirit and letter of the law; for, as Dr. Billington has so forcibly made known in his discussion on the treatment of diphtheria, it is in the little details in the care of the diphtheritic patient that success is obtained, and the neglect of these has caused many to abandon this plan for more heroic measures, or to content themselves with a constitutional remedy alone, and thus have they swelled the death-rate. Some, again, have carried out this plan of treatment in every particular, and seen, as I have seen, the disease leap from the tonsil to the pharynx, mount the pillars of the fauces, rage over the whole surface of the palate, rush into the posterior nares and Eustachian tubes to the middle ear, and, like a lurid demon, curl down into the larynx, as if mocking human opposition.

The nostrils are plugged up with diphtheritic exudation; this is washed away, and epistaxis follows. This is controlled. The disease goes down the trachea into the bronchi; rapidly, but secretly, the patient's system is being overwhelmed by the absorption of diphtheritic poison, unknown to the physician, threatening paralysis or cardiac thrombosis.

The little patient gets up from its cot, walks across the floor, and is seated in a chair to have its nose and throat washed out. You turn away for a moment to fill your syringe, then seat yourself before the child. A sad surprise seizes you—the little head drops on the shoulder, the face becomes purple, the eyes glassy. You lay the child quickly and gently on its cot, and hastily take out your hypodermic syringe—too late, the little sufferer is dead.

Another and another, and yet another case with like result, and the treatment is abandoned. But this is not, to my mind, a conclusive test either for or against any plan of treatment, because each case may have been of the most malignant type, or of that type necessarily fatal under any plan of treatment.

Again, you may have cases of the more simple type where any plan of treatment, or no treatment at all, would have been followed by recovery. I consider it necessary, therefore, to have at least twenty or more cases to treat, and the given plan to be strictly followed in each case, to fairly decide as to the efficacy of any plan of treatment.

Without entering upon a discussion of the etiology or pathology of the disease, I will here observe that I had been taught, and fully believed, that diphtheria was primarily a constitutional disease, having a local expression in the throat and glands of the neck. My own experience, however, in the treatment of cases in common with Dr. Billington, and subsequently in the treatment of many other cases while Visiting Physician to Demilt Dispensary, has had the effect of entirely changing my old theories. I became convinced that diphtheria was a local disease with a constitutional expression, and all subsequent observations have confirmed and strengthened this conviction.

During the spring and summer of 1881 and 1885, while I was Visiting Physician for the south district of Demilt Dispensary, I was called to see the following thirty cases of diphtheria, each one of which was seen by Dr. Billington and others, experienced in the treatment of diphtheria, who confirmed my diagnosis.

I will here beg your indulgence for a few minutes while I read in detail the history of three or four cases, which I personally attended, and which I believe justify my change of views on this subject:

Case 4.—I was called to see S. C——, aged four, June 12, 1881. Three or four weeks previous I had treated patient for scarlet fever. The condition of this patient was very bad. When first seen the diphtheritic exudation covered both tonsils, palate, pharynx, and extended into the nostrils. Temperature, 103½, axillary; respiration, 30; pulse, 140; fetid breath. Vomiting any liquid or food taken into the stomach. Albumen in the urine. Treatment as given above, with a diet of milk and lime-water to be given immediately after syringing out the nose and throat.

June 13th, P.M.—Patient did not vomit after the first thorough syringing of the nose and throat, and had swallowed nearly a quart of milk during the twenty-four hours. Temperature, 101; respiration, 22; pulse, 120. From this on the patient did well.

June 18th.—Examination of patient showed no diphtheritic exudation either in the throat or nostrils; but the urine was scanty and dark-colored, containing a large quantity of albumen.

Cases 5 and 6.—Brother and sister of Case 4, aged eight years, and eighteen months respectively; took the disease June 15th. Both cases were of the tonsillar and naso-pharyngeal type. The disease in both commenced

Thirty Cases of Diphtheria.

No. of case	Name.	Age.	Date of attack.	Date when first seen	Character of the disease.	Treatment	Duration of disease.	Result and remarks.
1	Kate T——.	5 years.	1881. May 2.	1881. May 3.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	6 days.	Passed out of my hands at my second visit, and died on the sixth day of the disease.
2	Mary D——.	8 years.	May 21.	May 22.	Tonsillar and pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	11 days.	Recovered.
3	Joseph K——.	8 years.	June 1.	June 1.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	8 days.	Recovered.
4	Samuel C——.	4 years.	June 10.	June 12.	Tonsillar, naso-pharyngeal, and laryngo-tracheal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	9 days.	Patient died on the ninth day from œdema of the lungs.
5	James C——.	1¼ years.	June 15.	June 15.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
6	Kate C——.	8 years.	June 15.	June 15.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	8 days.	Recovered.
7	James McM——.	6 years.	June 13.	June 15.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	6 days.	Recovered.
8	Bernard K——.	4 years.	June 17.	June 18.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	4 days.	Died suddenly on the fourth day of the disease.
9	James S——.	5 years.	June 25.	June 26.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
10	Rose R——.	4 years.	June 28.	June 29.	Tonsillar and pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	8 days.	Recovered.
11	Maggie O'B——.	13 years.	June 28.	June 30.	Tonsillar and pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	8 days.	Recovered.
12	Frances McG——.	5 years.	July 7.	July 10.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	14 days.	Recovered.
13	Anna B——.	3 years.	July 14.	July 16.	Labial, naso-pharyngeal, and laryngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
14	Mary T——.	2 years.	July 23.	July 25.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	13 days.	Recovered.
15	Edward C——.	5 years.	July 26.	July 26.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	11 days.	Recovered.
16	Michael D——.	6 years.	July 28.	July 29.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
17	Maggie S——.	2 years.	August 6.	August 8.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	12 days.	Recovered.
18	Daniel S——.	5 years.	August 9.	August 9.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
19	Ellen S——.	7 years.	September 22.	September 23.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	8 days.	Recovered.
20	Anna H——.	4 years.	September 22.	September 23.	Labial, tongue, naso-pharyngeal, and laryngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	11 days.	Recovered.
21	Marian B——.	10 months.	October 3.	October 4.	Naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	7 days.	Recovered.
22	Bridget F——.	5 years.	October 4.	October 5.	Tonsillar and pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	6 days.	Recovered.
23	John McA——.	3 years.	November 2.	November 3.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	7 days.	Recovered.
24	John S——.	3 years.	November 5.	November 7.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	7 days.	Recovered.
25	Peter M——.	7 years.	November 15.	November 18.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
26	Charles A——.	5 years.	December 9.	December 11.	Naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	7 days.	Recovered.
27	Michael D——.	4 years.	December 12.	December 14.	Naso-pharyngeal and laryngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
28	Ernest H——.	6 years.	December [illegible].	December [illegible].	Laryngo-tracheal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	10 days.	Recovered.
29	Francis H——.	3 years.	June 12.	June 13.	Laryngeal, tracheal, and [illegible].	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	5 days.	Died.
30	Samuel H——.	5 months.	June 15.	June 16.	Tonsillar and naso-pharyngeal.	Salt water and borax, with syringe-atomizer; iron and potass. chlorate, as per formula given above.	7 days.	Died.

June 19th.—Patient was allowed to leave his bed and go out into the yard.

June 21st.—I was called in the night to see the little patient, and found him in the last agonies of death with œdema of the lungs.

on the tonsils, spread to the palate and pharynx, and into the nostrils. The same treatment was carried out as in Case 4. In neither case did the temperature rise above 101½° F. Both made a good recovery, one in eight and the other in ten days.

Case 8.—B. K——, aged three. Was called to see this case on the second day after the attack. Disease tonsillar and naso-pharyngeal. Breath, fetid; temperature, 103°; respiration, 30; pulse, 140. This little patient was very intractable, so that I was never able to satisfactorily syringe out his nose and throat. He fought me to the last, and died suddenly on the fourth day of my attendance on him.

Case 12.—Was called July 9th to see F. McG——, aged nine. Patient first seen by me on the third day following the attack. Examination showed that the disease had spread from the tonsils to the palate, pharynx, and into the Eustachian tubes as well as the nostrils. Complete nasal stenosis. Palate and uvula very much swollen. Breathing rapid, stertorous, and breath extremely offensive. Temperature, 104°. Patient complained of severe pain in both ears. This patient was very refractory. It required the united efforts of my assistant, nurse, and the father of the patient to hold him in a chair while I syringed out his throat and nostrils. The relief to the patient was so great that two hours afterward the nurse had no trouble in using the syringe and atomizer alone.

July 11th.—Patient much improved. Temperature, 100°; respiration, 22; pulse, 98. Exudative material almost entirely cleared from the throat. Palate ulcerated through on both sides of the uvula, so that I was able to pass my lead-pencil through the holes. Both drum-heads ulcerated, and ears discharging freely.

July 12th.—After syringing out the nostrils quite a severe epistaxis followed the operation, but was soon controlled by the use of ice. From this on the patient did well, and convalescence was fully established on the fourteenth day of the disease.

Case 13.—Was called to see A. B——, aged two and one-half, July 16th. Examination of the throat and nostrils showed no signs of diphtheria, but on examining the inside of the lips I found several spots of diphtheritic exudation. The disease spread to the tongue, tonsils, pharynx, nostrils, and larynx. The same treatment as in the other cases, with recovery on the tenth day of the disease.

Case 21.—Was called to see M. B——, aged ten months, October 4th. Patient unable to breathe through the nostrils. Nursed with difficulty and had frequent attacks of vomiting. Examination of the throat showed no signs of diphtheria. Temperature, 103½°; respiration, 38; pulsation, 140. Examination of the lungs gave negative results. I suspected nasal diphtheria and prescribed the usual treatment. In syringing out the nostrils the solution would pass into the throat.

October 5th.—Patient in much the same condition. Examination of the throat showed a few patches of diphtheritic membrane upon the pharynx, none to be seen on either tonsil. While syringing out the nostrils, suddenly one nostril became completely blocked up and a small portion of the diphtheritic membrane protruded from this nostril, which required considerable force with a pair of forceps to extract it. When spread out on a cloth this piece of membrane measured one inch in diameter and was about one-fourth of an inch in thickness and gave a perfect cast of the posterior nares and soft palate.

October 6th.—Patient much improved; nursing without difficulty; no vomiting; breathing about normal, and temperature 99½° F. From this time on patient did well, and convalescence was fully established on the seventh day of the disease.

In referring to Cases 28, 29, and 30, I wish to bring out a point in tracheotomy for membranous croup, so called, but which my experience has taught me to call diphtheritic laryngo-trachitis. In the above cases, the occurring as they did within two weeks of each other, and in the same family, leaves no doubt on my mind as to the nature of the disease.

In Case 28, on the second day of the disease, when the breathing became very labored, pulse rapid, temperature 103°, and the features showing a want of proper aëration of the blood, I suggested tracheotomy to the parents. They would not permit the operation. The same treatment as in the preceding cases was followed. To my surprise the patient made a good recovery in ten days, except a slight hoarseness, which lasted for two or three weeks.

Case 29 was attacked, three or four days following Case 28, with precisely the same symptoms, and died on the fourth day of the disease without tracheotomy. The treatment was the same as in the former case. Hence, had I done tracheotomy in Case 28, and he had lived, as he did without it, and then have omitted to do the operation in Case 29, I would doubtless have been wedded to the operation, which I am not.

One week following the death of Case 29, Case 30 was attacked with the disease. Its first appearance was seen on the tonsils; it rapidly spread to the palate, pharynx, and nostrils, made its appearance on the genitals, and the little patient succumbed on the seventh day of the disease.

I think there can be no doubt as to the nature of the disease in these three cases; yet Cases 28 and 29 were such as are regarded by dualists as typical of true croup rather than diphtheria.

It is proper that I should say that Dr. Billington claims nothing specific or new in the remedies, nor does my own experience lead me to believe that there is a specific for the cure of diphtheria known to the profession. However, Dr. Billington, believing the disease to result fatally if allowed to develop into blood-poisoning, and that this condition is superinduced by the absorption of decomposed gangrenous sloughs, adopted the plan of washing away the gangrenous discharge, cleansing the parts antiseptically, thoroughly, and often. The efficacy of this treatment as a preventive of blood-poisoning is most conclusively attested by the hundreds of cases it has saved, and these, too, under the most unfavorable conditions, surrounded by filth and foul air in the wretched houses of the poor of New York. In the treatment of a small number of cases there can be no just estimate formed of the value of any method of treatment. It not infrequently occurs that the first few cases coming under our observation are of a desperate character, or it may be that we are not called in until the disease has reached a stage when the system is almost overwhelmed with blood-poisoning. In these cases and at such times any plan of treatment may fail, and then we are too apt to abandon the course pursued as unavailing, or no better, at least, than other plans which have been advanced and resulted in failure. We may then solace ourselves with a few severe reflections on the fact that the highest authorities have always pronounced diphtheria a most fatal disease; that the County and State Medical Societies have reiterated this verdict, and that statistics have fixed its death-rate at no less than fifty per cent.

Confronted by this alarming rate of fatality, I determined at the outset of my contact with diphtheria to scrupulously avoid vacillating or experimenting with different forms of treating the disease, but firmly adhered to the one form in which I had fullest confidence. I considered that the results from at least twenty or thirty cases treated were necessary before an intelligent judgment could be reached—before the plan adopted should be pronounced a failure. Therefore, when I assumed the duties of Visiting Physician of the south district of Demilt Dispensary, I decided to observe the very spirit and letter of Dr. Billington's plan of treatment. This means something more than an occasional spray of carbolic acid and lime-water, with a semi-occasional injection into the nostrils and throat of a spoonful of the salt-water solution. It means more than this, if it means anything. It means that the parts affected must be thoroughly cleansed with the syringe, using in some cases a pint of the salt-water solution for each sitting, and at in-

tervals not exceeding two hours, and using the atomizer every half hour. Herein lies the success of this plan of treatment, as without a judicious thoroughness in applying the syringe the throat becomes filled with the gangrenous discharge, and the nasal passage completely blockaded; so that respiration is carried on through the mouth. In this suffering condition I have frequently found the patient on my first visit; a condition pre-eminently favorable for absorbing the poisonous discharge. Then allow no time to be lost in preventing or stopping such absorption, or the gravest consequences will ensue. I use a common hard-rubber ear syringe, with the tip of the nozzle cut off for cleansing the throat and nostrils.

With the inexperienced a mistaken diagnosis is frequently made in dealing with diseases of this class. A simple catarrhal pharyngitis is sometimes termed diphtheria, and again, follicular tonsillitis is mistaken for the same disease. When the muco-purulent discharge is thrown out from the follicles, besmearing the tonsils, and even the pillars of the fauces, drying and gluing itself to the parts, it presents to the eye of the casual observer the appearance of a marked case of diphtheria, as it resembles the plastic effusion thrown out by the diphtheritic process, or in the case of follicular tonsillitis, where the inflammatory process within the follicles has been so destructive that we find two or more follicles coalesced and surrounded by the débris of the broken-down walls, the appearance is again much like that of the destructive process of diphtheria; but by judicious syringing of the tonsil you will be able to wash away the exudative material and broken-down tissue and bring into view each inflamed follicle; and this, as in all other inflammatory products of the throat, not diphtheritic, we are able to remove by the aid of the syringe. However, I think in two of my cases the disease started first as a follicular tonsillitis, and afterward, being in a locality where diphtheria existed, they became cases of diphtheria.

Before closing, permit me to state that in not a single case did I deem it necessary, neither did I give one drop of alcoholic or other so-called stimulants, nor one grain of quinine or other so-called antipyretics. In each and every case I adhered to a strictly milk diet until convalescence was well established.

CLAVICLE SPLINT.

By A. P. MITTEN, M.D.,

COLUMBUS, IND.

Dr. Smith's apparatus for fracture of the clavicle, as shown in The Medical Record for December 19, 1885, will evidently accomplish but *two* of the three essential requirements in that fracture. It will elevate the shoulder and carry it outward, but will *not* carry it backward; the latter direction being most essential in a vast majority of the cases. As must inevitably be the case where the arm is used as a lever and the chest as a fulcrum, the position is irksome and uncomfortable; unbearable, in fact, in some cases. The fact that from the time of Hippocrates to the present time eminent surgeons have advised placeing the patient in bed, with little or no dressing, is but a confession of inability to apply satisfactory apparatus to this injury.

The accompanying cuts will show the apparatus I have used with entire satisfaction. I will briefly describe it, and mention what I claim as points of superiority, and let its application, by those who may consider it worthy a trial, be the test of its merits.

1, in Fig. 1, a board half an inch thick, eight to ten inches wide, heavily padded on one side, and eighteen inches long. 2, six inches wide, from sixteen to eighteen (or according to size of patient) inches long, half an inch thick, this securely fastened to upright splint, as shown; a notch in the upper and lower side near the ends; two belts made of wide surcingle material tacked upon the upright, as shown in Fig. 1, and buckled in front, as shown in Fig. 2; two pieces of unbleached muslin about four inches wide and one yard long, folded and sewed, and stuffed with bran for a distance of about six inches at the middle; these passed over each shoulder, 3, 3, in Fig. 2, and securely tied over the end of the cross splint. The shoulders are now carried upward, outward, and

Fig. 1.

backward. The clothing can be put on and the arm supported in a sling, and, if need be, secured to the side. The roll over the shoulder should be flattened from before backward, and to prevent slipping in either direction, inward or outward, the under surface should have stitched to it a piece of rubber adhesive plaster about two inches wide and six inches long, the adhesive surface of course being directed to the shoulder. If the action of the sterno-cleido-mastoid muscle should elevate the inner extremity of the bone, a compress can be applied

Fig. 2.

by means of a strap of adhesive plaster. 1. It does away with the axillary pad. 2. It fixes the scapula and the entire shoulder-joint. 3. It avoids fixing the elbow-joint in a constrained and painful position. 4. The patient can put on and remove his clothing without disturbing the dressing. 5. The patient can attend to his ordinary daily

wants, as slight movements of the arm and hand can be made without injury, as such motions stop at the head of the humerus. In conclusion, the injury being a simple one and unattended by danger, and so considered by the laity, it becomes all the more necessary to make the apparatus used in its treatment as simple and as comfortable as is consistent with the accomplishment of its purpose.

Clinical Department.

CONVULSIONS IN AN INFANT CURED BY MORPHINE.

Dr. H. Plummer, of Harrodsburg, Ky., reports the case of an infant, twenty-two months old, who was seized, after a short period of malaise, with convulsions. She was seen after the second convulsion, and did not then appear to be very ill, but was fretful; the temperature was 102°, and there was some little cough, but there were no signs of pneumonic trouble. Bromide of potassium in five-grain doses was given every hour, but the convulsions increased in severity and frequency. The bowels had been moved by calomel and castor-oil. In the afternoon of the second day the child was in the following condition: The tongue was protruded between the teeth, swollen, and constantly in motion; the forearms were flexed and rigid, the thumbs being firmly drawn into the palms, and the lower extremities were likewise rigid; the child was now unable to swallow, and the pupils were widely dilated. The convulsive attacks recurred at such short intervals that they seemed to be continuous. Other remedies having proved ineffectual, Dr. Plummer determined to employ morphine, and accordingly gave one-sixth grain hypodermically. In a few minutes the little patient fell into a sleep, in which she remained, awaking only to drink, for twenty hours, the pupils became of nearly the normal size, and the muscular system became relaxed. From this time she continued to improve, although she seemed nervous and fretful for a time, and the convulsions did not return.

CLINICAL FEATURES OF TWO CASES OF PSEUDO-HYPERTROPHIC SPINAL PARALYSIS.

Dr. C. Eugene Riggs, of St. Paul, Minn., reports two cases of this affection, having an interesting family history. The patients were brothers. The first boy, aged six, had a peculiar waddling gait when walking, and marked lordosis of the spine, with consequent protrusion of the abdomen. Upon falling to the floor he was unable to raise himself to the erect posture, and attempts to do so caused pain in the back. He could not talk plainly, and the tongue remained more or less protruded from the mouth. The patient complained of pain through the eyes and temporal region at times, and also of some pain in the calves of the legs. The circulation seemed sluggish in this portion of the body, and the skin presented a mottled appearance, and remained white for some time after pressure had been made. The hypertrophy of the muscles was much more marked upon the left than the right side, the only exception to this being in the legs, which measured the same, although nine months ago the left was half an inch smaller than the right. The calf was the only portion of the right limb hypertrophied. Upon the left side the muscles on the posterior portion of the thigh and the glutei muscles were hypertrophied. The muscles of the back, especially those on the left side, were undergoing apparent hypertrophy, as were also the left deltoid and the tissues of the cheek on the same side. The left forearm measured half an inch more than the right.

The following measurements show the degree of hypertrophy in the second case, a boy, aged four: Upon the right side the arm, forearm, thigh, and calf measured, respectively, 3½, 5½, 11, and 6 inches in circumference, while upon the left side the figures were 6, 6, 11½, and 6.

In this case the hypertrophy was on the anterior portion of thigh. Patient was able to walk, but with the characteristic gait. After falling, he was able to resume the erect posture by raising himself first upon his feet and hands, and then, approximating the two extremities, climbing up his legs by his hands. During this effort he complained of some pain in the back. The mother of these children states that neither of them walked until he was two years of age, and never crept, but only "hitched along from one object to another."

The following interesting family history was given by the grandmother of the patients, an intelligent old lady, eighty-two years of age, seemingly herself suffering from a partial paralysis of the flexor muscles of the thigh. Her grandmother was the mother of ten children, nine daughters and one son. None of this family manifested any symptoms of this disease, as far as known, though the son entered the army at the age of twenty and all trace of him was lost. Several of the daughters reached adult age, married, and bore children. The males were all victims of this disease. Mrs. S—— (the lady giving the history), of the next generation, had ten sisters and one brother; the latter began to show symptoms of the disease at the age of ten years, and died in his twentieth year. As the disease progressed, his thighs became flexed upon the abdomen, and the legs upon the thighs. For a week prior to death there was no fecal evacuation, but a continual hemorrhage from the bowels. Two hours before death the patient suffered extreme pain throughout the body; this continued about an hour, and during the last hour there was no pain. The intellectual faculties were retained to the last. Mrs. S—— is the mother of eleven children, four daughters and seven sons. Two of the former died young, a third was the mother of one child, a son, who died of this disease. The mother died of cancer. The other daughter was the mother of the subjects of this report. Five of Mrs. S——'s sons died of the disease. One of them, who lived a comparatively longer time than the others, had the thighs firmly flexed upon the abdomen, and the legs upon the thighs, and the spine was curved to such an extent that the back of the head was within eight inches of the buttocks. The other two sons, now between thirty and forty years of age, are free from the disease. This history covers a period of more than one hundred years, and shows the heredity of the disease and its tendency to follow the males from one generation to another. In the two cases reported there was a condition and a symptom which Dr. Riggs has not seen mentioned in works upon this disease, namely, the hemi-hypertrophy of the left side, and the pain in the back. The former was well marked in both cases, as shown by the measurements, and the latter was one of the pronounced symptoms complained of by the patients.

ACCIDENT TO A PREGNANT WOMAN, RESULTING IN FRACTURE OF THE SKULL OF THE FŒTUS—RECOVERY OF THE MOTHER.

The following case is reported by Dr. George Lunney, of Malden, Mass.: A lady, aged twenty-three, who was within about ten days of the completion of gestation, while opening a door slipped and struck the edge of the door with great violence against her side in the right lumbar region. She was seized with a feeling of faintness and nausea, which continued for some hours, and then recurred at intervals for three days. Prior to the fall the child had given frequent evidence of life, but since that time it had been motionless, and the abdomen, which had hitherto been "warm," now felt, as the patient expressed it, "cold and unnatural." Examination showed a long, narrow line of contusion, extending from the lower part of the right lumbar region to the upper part of the umbilical region. Eight days after the accident labor be-

gan. After the spontaneous rupture of the membranes an examination was made, and revealed the presentation at the os of an angular, irregular mass, which a little later was recognized as a comminuted, disarticulated skull within an unbroken scalp. Labor progressed very slowly, and, as it was impossible to apply the forceps to the presenting part, a dose of ergot and whiskey was given, and delivery accomplished by pulling on the scalp with the hand, the vagina being at the same time protected from injury by the sharp angles of bone.

On examination of child a complete fracture of the left half of the frontal bone was found, extending from the supra-orbital foramen in front, passing backward and slightly inward—nearly equidistant from frontal suture and temporal ridge—to the coronal suture.

The left parietal bone was also broken, the fracture extending from a little to the left of the anterior-superior angle in front, passing backward over the parietal prominence and terminating a little to the left of the posterior-superior angle. Many of the other bones of the cranium were fractured or disarticulated. The woman made an excellent recovery without a single untoward symptom.

GUNSHOT WOUND OF THE HEART.

Dr. S. V. Hoopman, of Baltimore, writes: "On Christmas afternoon a man was shot in the chest. The ball was a No. 38. Death occurred nineteen and three-quarter hours after the shooting; the post-mortem fifteen hours after death. The bullet entered the chest to the left of the sternum, perforating the fifth rib. It then passed through the pericardium, left ventricle, and lower lobe of the left lung, it then passed out of the chest, fracturing the eleventh rib, and was found in the muscles of the back. *One* ounce of blood was found in the pericardium, and *fourteen* ounces in the *left pleura*."

Progress of Medical Science.

The Trigeminal Cough.—This peculiar term, introduced by Schadewald, signifies the cough which in perfectly normal conditions of the larynx and lungs persists with the greatest constancy day and night, being caused by the slightest temperature changes and in presence of penetrating odors. Sneezing and snuffling are the constant attendants of this trigeminal cough, which can even be artificially produced by gently tickling the nares. The patient will at once be forced to cough violently, and will recognize the cough as identical to the one which usually torments him. The frequently occurring cases of persistent coughing, without any traceable implication of larynx and lungs, which can be readily provoked by touching the termination of the trigeminus, are all to be regarded as pertaining to the trigeminal cough. The paroxysm of the trigeminal cough has a striking resemblance to the purely nervous asthmatic attack, beginning and ending with a paroxysmal cough. Still, in the asthmatic paroxysm we find a different acme as to duration and mode of respiration. Wille regards the purely nervous asthma as a simple reflex neurosis of the trigeminus in its nasal branches, and, according to his observations, we find the nervous asthma always accompanied by a trigeminal cough. Hence many cases of asthma can be, and have been, cured by cauterization of the nasal mucous membrane. The trigeminal cough can be divided into a nasal, a pharyngeal, and an auricular one. The cough which sets in if the external auditory meatus is being cleansed or irritated, is by no means a vagus cough, as has been assumed before; for the anterior portion of the meatus is not supplied by the vagus, but by the auriculo-temporal branch of the infra-maxillaris, hence by a subdivision of the trigeminus. This cough, therefore, is to be regarded as a typical trigeminal cough. The nasal form of trigeminal cough, however, is that most frequently met with. In all cases in which we find an obstinate cough, and yet are unable to discover any organic alterations, a trigeminal neurosis should be thought of. In the trigeminal cough, as in the asthmatic paroxysm, the neurotic affection is the principal fact, and not, as some authors have asserted, some possibly visible anatomical alterations of the mucous membrane, such as tumefaction of polypi, etc. Not only the direct cauterization of the nares, but even the simple sounding, executed sufficiently roughly to provoke epistaxis, suffices to produce an improvement of the neurosis. The therapeutic success of iodide of potassium in nervous asthma, which is actually but an intense nasal trigeminal neurosis, is to be explained by the hypersecretion of the part excited by the drug, which assists in the elimination of foreign irritations and bodies from the affected tissues. As the best mode of treatment of trigeminal neuroses the galvanization of the nasal nerves with a weak induction current has been warmly recommended. In lighter cases a resolving treatment, with the nasal steam-douche and the internal administration of iodide of potassium, will be sufficient. The sneezing and snuffling produced by this drug is the very thing desired. Wille formulates his general conclusions on this subject as follows: 1. The trigeminal cough is by far the most frequent type of all existing coughs. 2. It is a nasal reflex neurosis, and may be regarded as the pathological inversion of the sneezing act. 3. This neurosis may exist with or without anatomical alterations of the nasal cavities without being dependent upon them. 4. The highest expression of this neurosis is the nervous asthma. 5. This reflex can be provoked by all branches of the spheno-palatine ganglion, and by the ethmoidal nerve. 6. Every local treatment in the domain of the trigeminus, which alters its reflex functions, may lead to an improvement or even a cure of the affection.—*The Therapeutic Gazette.*

Hysteria in Children.—The following are the conclusions of Dr. Peugniez, in a recent thesis on this subject (*Archives Générales de Médecine*, February, 1886): 1. Hysteria is not rare in children. 2. Heredity is the principal predisposing cause of the affection. 3. Disturbance of the moral faculties is one of the first symptoms observed. 4. The general symptoms are nearly the same in children as in adults, whatever be the sex. 5. The results of treatment are usually more satisfactory in the child than in the adult. 6. The earlier the diagnosis is made and treatment instituted, the less grave is the prognosis. 7. Isolation is the most effective method of treatment of infantile hysteria. 8. The disease is sometimes epidemic in character.

The Treatment of Congenital Syphilis by the Older and Newer Methods.—Professor Monti, of Vienna, has published an elaborate paper on this subject. The following abstract (*London Medical Record*, January 15, 1886) embodies the chief points made by the author. Of treatment by inunction, the oldest is that in which blue ointment is employed. It is still largely used, but the objection to it is that it oxidizes too readily in this form, and is then apt to produce eczema. Oleate of mercury is extensively used instead of the blue ointment, and mercurial plasters have been substituted by some, while Charcot recommends mercurial soap. All those compounds are, however, more or less unsuited to the tender skin of infants, the least objectionable being the oleate of mercury. Dr. Monti has, however, had no personal experience of the soap. Moreover, inunction involves considerable risk of the system rapidly absorbing an excessive quantity of the drug, and in the case of very young infants this leads to acute anæmia. He has also come to the conclusion that the sudden death, which is not an uncommon incident in hereditary syphilis, occurs with far greater frequency where this has been treated by inunction. For these reasons he has for some years ceased to use it in the case

of children under one year. The next treatment under review is that by calomel. This also has a tendency to produce anæmia, and should, therefore, be given as a powder in combination with lactate of iron. This should be discontinued when the first symptoms have disappeared, and saccharated iodide of iron substituted until the spleen is no longer felt or the skin has resumed its normal color; but should the disease reappear in the skin, mucous membrane, or bones, calomel must again be resorted to. In some rare cases, such as those where there is great irritability of the intestinal tract, a subcutaneous injection of a freshly prepared mixture of calomel suspended in mucilage may be administered. The treatment by corrosive sublimate gives very satisfactory results, provided it be not too long continued, in which case symptoms of gastric irritation will supervene. This drug is also administered in the form of a bath, which should contain about seven grains; but in the writer's experience their effect upon the disease is very slow, and should, therefore, be accompanied by calomel internally, and in that way they appear to hasten the cure. The best mode of giving corrosive sublimate is by subcutaneous injection. The solution should consist of perchloride of mercury, gr. jss.; chlorate of soda, gr. vj.; and water, 150 grains, and of this one-half to one syringeful should be used every day, or every other day, until the symptoms disappear, to be renewed upon their return. The punctures are best made upon the abdomen or chest, and must not be too close together. The injection is in general well borne, and according to Dr. Monti's experience never produces mercurialism and causes very little loss of flesh. It cannot be denied, however, that infants do not bear these injections so well as adults; even with the greatest care it is not uncommon to find induration of the cellular tissue and abscesses at the seats of puncture. It is also not suitable for out-patients, because the mothers decline to bring the children after the first few times. Notwithstanding that the symptoms subside more rapidly under this treatment than under any other, the author has of late confined its use to cases that would not bear mercury internally. Albuminate of mercury, as recommended by Bamberger, is preferable for hypodermic use to corrosive sublimate, provided the solution be clear, but it is excessively unstable, and, if used in a cloudy state, produces irritation and abscesses. Much the same objection applies to mercury-peptone, though it is rather more stable. Formamide of mercury (Liebreich) is unsuited to children. Protiodide of mercury produces excellent results, especially when combined in a powder with lactate of iron, and perhaps no other remedy acts so promptly upon syphilitic affections of the bones. Unfortunately it produces diarrhœa and colic, and the addition of Dover's powder to the above compound soon ceases to have any effect. Consequently Dr. Monti only gives it in cases where bone-affections exist from the beginning. Black oxide of mercury, as recommended by Henoch, was found to produce vomiting, and was therefore soon given up. The author has had only a limited experience of hydrargyrum tannicum oxydulatum (Ludwig), but is favorably impressed by it, more especially because it does not appear to affect the digestive organs. It is now a recognized fact that hereditary syphilis can be cured by preparations of iodine as well as, though more slowly than, by mercury. The author is very favorably impressed with the saccharated iodide of iron. He says that it is well borne by children of any age, improves their nutrition, and never produces iodism; but it is much slower in its action than mercury, and is therefore best suited for very chronic cases. It should be given as a powder, for if the syrup be used it is apt to produce diarrhœa. Three grains may be divided into ten powders, and a new-born child may have two or three daily, dissolved in milk.

Broncho-pneumonia in Cholera.—M. Dubreuilh writes ("Thèse de Paris," 1885), that broncho-pneumonia of insidious and rapidly progressive course not infrequently occurs during the period of reaction of cholera. It may be latent and only discoverable through a small number of symptoms, and even then only on the eve or the day itself of death. The most frequently observed symptoms are an acceleration of respiration and pulse, rusty sputa, pain in the side, and especially the physical signs, subcrepitant râles, rarely a blowing sound, and dulness on percussion. Notwithstanding the rapid evolution of the disease, the lesions are very extensive. Broncho-pneumonia may be the actual cause of death, or it may be only an accessory in leading to a fatal issue. Recovery may take place, and when it does occur, the return to health is usually very rapid.—*Archives Générales de Médecine*, February, 1886.

A Successful Ovariotomy in the Seventh Month of Pregnancy.—Dr. N. N. Suslin reports the following case in the *Journal of the Kazan Medical Society* (Russian), December 31, 1885. A peasant woman, nineteen years of age, one year married, entered the clinic of Professor Levshin on account of an abdominal swelling which she had noticed for the past three years. She commenced to menstruate when sixteen years old, and had always been regular up to seven months before admission. At that time the abdominal enlargement began to increase very rapidly, and was now so excessive that when lying on her back the patient was unable to breathe, and she had for two months been forced to sleep reclining in a chair. The abdomen at the level of the umbilicus measured fifty-four and one-half inches in circumference. Two tumors could be felt, separated by a distinct depression. The mammary glands were enlarged, the nipples pigmented, and on pressure milk could be expressed. There were also other signs establishing beyond doubt the existence of pregnancy complicating an ovarian cyst. On the day after admission ovariotomy was performed, an incision being made in the linea alba, extending for a distance of eight inches between the umbilicus and pubis. The anterior surface of the tumor was found adherent to the parietal layer of the peritoneum, but the adhesions were not very firm and could easily be ruptured by the hand. The cyst, which was attached by a short pedicle to the right side, was drawn out and evacuated. The uterus lay posteriorly and on the left side, and was as large as it would normally be at full term. The pedicle was ligated and left within the peritoneal cavity, and the wound was dressed with iodoform. The dressing was removed on the tenth day, and the wound was found to have healed by first intention. The patient made a good recovery, and her pregnancy went on without disturbance to full term, when she gave birth to a healthy child. Nine days later she was discharged cured.

Primary Endocarditis in Soldiers.—All authorities agree that primary endocarditis is a very rare affection. The disease not unfrequently develops after pneumonia or pleurisy, in severe fevers, and in acute articular rheumatism, but it is very seldom seen to arise independently of these conditions from external causes. M. Fournier states, however, in an article in the *Gazette des Hôpitaux* of January 30, 1886, that he has observed it several times in soldiers, and believes that it is not seldom caused by chilling of the body during a halt after a long march or fatiguing evolutions. He relates a typical case taken from those which have come under his observation, and arrives at the following conclusions as a result of his studies in this direction: 1. Primary endocarditis, a very rare disease in the ordinary conditions of life, is much less infrequent in soldiers. 2. It is commonly developed in them through the influence of cold or fatigue. 3. Energetic treatment should be instituted at once, in order to prevent the deposit of fibrine upon the valves, which may lead in time to serious heart trouble. 4. The best mode of treatment consists in the application of wet cups over the region of the heart, followed by a blister. This treatment is usually followed by rapid amelioration.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 27, 1886.

THE INDICATIONS FOR EXCISION IN HIP DISEASE.

THE question as to how frequently the operation for excision of the hip should be performed when the joint is diseased is still an unsettled one. The application of antiseptic surgery, which has reduced the mortality from the operation itself, has in particular rendered a fresh study of the matter advisable. In the *Annals of Surgery* for January, 1886, Dr. Leroy M. Yale has reviewed the subject in a thorough manner, and has collected statistics which enable one to reach certain tolerably positive conclusions.

There has been no little difference of opinion among surgeons as to whether any operative interference is advisable, unless the patient has necrosed bone or is plainly suffering from extensive and severe disease of the femur or os innominatum. The tendency perhaps has been to operate quite often in suppurative coxitis.

The ground taken by those advocating excision is that it promotes early healing of the disease, lessens mortality, and gives a better limb functionally.

The general mortality from hip disease, judged by the reports of the New York Orthopædic Hospital and of the Hospital for Ruptured and Crippled, is not high—ranging from five to twelve per cent. of the cases.

The mortality from suppurative coxitis when no operation is done varies extremely, as shown by the following table: Hueter, 50 per cent.; Cazin (80 cases), 12½ per cent.; Taylor (private practice, 24 cases), 8⅓ per cent.; Ollier, the greater part recover; "London Clinical Society Report" (587 cases), 33½ per cent.; Caumont (19 cases), 63.1 per cent.

As the question of excision only arises after suppuration takes place, the statistics showing the mortality when this is done are very significant. They are as follows: Leisrink, 57.9 to 63.6 per cent.; Sayre (72 cases), 34.7 per cent.; Culbertson (418 cases), 41.62 per cent. (6.93 from operation itself); Cowell (65 cases), 10.77 per cent.; "London Clinical Society Report" (587 cases), 37.7 per cent.; Holmes (215 cases), 18.6 per cent.; Caumont (42 cases), 61.9 per cent. (11.9 from operation); Bryant (30 cases), 18 per cent.; Volkmann (48 cases), 8⅓ to 25 per cent. (antisepsis); Korff (33 cases), 48.8 per cent. (30 per cent. under antisepsis); Grosch (166 cases), 33.7 per cent. (antisepsis); Alexander, 30.55 per cent. (antisepsis).

From these figures it seems that there is not much difference, as regards mortality, whether excision is performed or not, and that the introduction of antiseptics has reduced the mortality six or seven per cent.

The tables given do not indicate the proportion of cases that are not benefited by the operation—that "relapse," or are unhealed. This is placed by Dr. Yale at about twenty per cent. Assuming, therefore, that about one-third die and one-fifth relapse, it follows that the successes in excision amount to only about fifty-three per cent. This is about the same as the percentage of cures given by Cazin in eighty cases treated expectantly, the cases being followed up for five years.

No very brilliant results, so far as cure is concerned, therefore, can be attributed to excision. As to the claim for better functional result, this has not at least a very strong basis. We are inclined to believe, from the evidence so far accumulated, that patients treated expectantly, as a rule, get a better limb. At the same time the operation of excision occasionally gives most brilliant results.

The conclusion reached by Dr. Yale is that excision is only indicated as a life-saving operation, in order to remove the dangers consequent upon long-continued suppuration.

APHRODISIAC ADVERTISEMENTS AT THE THEATRES.

THE medical press is almost alone in its fight against quackery, because, for one thing, quacks pay the daily press some seventy-five cents a line to convince them that our strictures and opposition spring merely from a spirit of selfishness and a trades unionism.

Sometimes, however, advertising quacks combine with their effrontery such manifest immorality that we can fairly venture to call the attention of the secular press and of the officers of the law to it.

A correspondent has sent us some specimen advertisements from the programme of a musical burlesque which is running under a certain kind of sensational management in this city and whose popularity is based mainly upon the almost complete denudation of the female characters.

The advertisement is for the "Turkish Aphrodasiac Golden Pills," or "The Secret of the Harem," the advertiser, as will be seen, in his search for positive cures having neglected the minor details of spelling.

Our correspondent writes: "The place where the remedy is advertised betokens very good judgment on the part of the owners of 'The Secret of the Harem,' as one might well imagine that, after a wine dinner, an evening spent in the study of infra-umbilical female morphology at this theatre might act as a powerful synergist to the phosphorus and cantharides in the "Aphrodasiac Golden Pills."

The worst part of this disgrace, our correspondent adds, "appears on the first page of the same programme, where ladies are requested to send their name and address to the same disreputable firm in Buffalo, when 'they will receive by return mail valuable information.' What this 'valuble information is it does not say, but probably it contains hints as to helping the 'Golden Pills' 'permit' the 'old men' to 'procreate.' It is unnecessaryto comment on the influence of such obscene stuff on the good or bad of both sexes.

A GREAT PATHOLOGICAL EXHIBITION.

At a recent meeting of the London Pathological Society, fifty cerebral tumors were exhibited by members.

The size, location, and morbid condition of the tumors was almost as varied as the number presented.

There certainly is a wide appreciation of the fact, that the study of the morbid anatomy of the brain will give us a key to many of the physiological processes of that organ. Unfortunately, the tumors in most cases spread themselves to such an extent, involving so much of the brain-substance, that it is difficult to disentangle the symptoms belonging to the various areas involved.

The *British Medical Journal* thus summarizes the one generalization which, it says, can be drawn from the London Exhibit: "A tumor may occur in any region of the brain, that the region within which symptoms permitting localization occur is very limited, and that, therefore, surgery can do nothing for a large proportion of the patients who suffer from such tumors."

Such a method of investigating morbid anatomy, whether of the brain or any other organ, is a very practical one. It arouses interest, brings the minds of a learned body like a pathological society to bear upon one subject, which insures a preparation and ability to discuss questions which one would naturally hesitate to do offhand.

POSTURE IN THE REDUCTION OF HERNIA.

It needs no argument to prove that prevention is better than cure, or that it is better to reduce a hernia before strangulation has occurred than to operate after this condition has become established. Much has been written about the best methods of taxis; but the advice is almost always given to push up the prolapsed gut, and the utility of traction in effecting reduction is seldom considered. Most writers, it is true, recommend that the effort be made to relax the abdominal walls by means of an anæsthetic, and many advise that the patient be inverted if taxis in the dorsal position have failed in its object. But posture, if it be mentioned at all, is usually referred to only incidentally and as a last resort after the attempts to push back the intestine have proved fruitless, and the prime necessity of reducing intra-abdominal pressure seems in a measure to have been overlooked.

In an article in the *Centralblatt fur Chirurgie* of February 6, 1886, Dr. Karl Nikolaus notes this omission, and calls attention to a method which he claims to be at once rational and effective. Every-day experience demonstrates how unsatisfactory in many cases is taxis, as commonly employed, and that it should so often be ineffective is shown by a simple experiment. A portion of intestine about three feet in length is passed through a piece of rubber tubing two inches long. If now one end of the gut be filled with water it will be found impossible to force the fluid by means of pressure through the constriction formed by the rubber tube, but let suction be made on the empty extremity and the water will readily pass. And again, a knuckle of empty intestine can with great difficulty be pushed through a rubber tube, although it can be drawn through the same tube with ease. In like manner a prolapsed knuckle of intestine may resist every effort made to push it back through the constricting ring, but reposition will take place spontaneously when a traction force is substituted for pressure.

The necessary traction force is to be obtained by reducing intra-abdominal pressure. But this is not effected by simple relaxation of the abdominal walls, for the abdominal parietes may be made very lax by placing the patient on his back with the thighs flexed and the thorax elevated, but in this position the capacity of the abdomen may be so much diminished as even to increase the pressure. The position which the author recommends is that known as the knee-shoulder position, the patient resting upon his knees and upon the shoulder on the sound side. Or, if this is for any reason impracticable, the Sims position may be assumed, the patient lying upon the side opposite to the hernia and with his pelvis raised. The intra-abdominal pressure may be still further reduced by previously evacuating the bladder and rectum. While the patient is in this position a considerable suction force is exerted to empty the incarcerated gut of its contents, and then the intestine will often be drawn back into the abdominal cavity by a continuation of the same force combined with that of gravity.

Dr. Nikolaus has succeeded by this means alone in effecting reduction in a considerable number of cases of hernia after taxis had been tried in vain. The method would seem to deserve a more prominent place in the therapeutics of hernia than it has hitherto occupied, and it might, at least, be tried first, before resorting to prolonged taxis, which is, even in experienced hands, by no means always a perfectly safe and harmless procedure.

THE QUESTION OF LATIN.

It is not in this country alone that the opponents of a so-called classical education are active, but they are making themselves heard also in older lands and among people whom we are accustomed to regard as less practical and more wedded to tradition than ourselves. A work entitled "The Question of Latin," has recently been published by M. Raoul Franz, in which he asserts that the time spent in the study of this language is, for the great majority of educated men—physicians as well as others—simply time thrown away. It would be much better, he thinks, were students to employ the hours now devoted to Latin, in the acquisition of more practical knowledge. The arguments which the author brings forward in support of his position are familiar to all those who have given the subject any study; but though not new they are presented in such an attractive way as possibly to force conviction upon many whose opinions are as yet unformed.

It can hardly be questioned that, as Latin and Greek are now taught in school and college, they might with advantage be dropped from the curriculum. But the remedy is not to abolish the study, but to reform the system. There is no necessity of devoting six or eight years to the study of a language, even a dead language, in order to acquire a good working knowledge of it, when by the use of the modern methods a better result can be obtained by one, or at most two, years' application. While fully recognizing the advantage to a physician of a knowledge of French and German, we do not believe that the study of those tongues can be made to take the place of a groundwork in Latin. Education is a training,

and one who has had the mental discipline furnished by a proper study of Latin will find that he has acquired a facility for mastering modern tongues which another will not possess. And furthermore, he will have become possessed of habits of observation and reasoning which will be of incalculable advantage to him in the practice of medicine as well as in other pursuits.

LITERARY EVOLUTION.

We greatly err in supposing that evolution obtains merely in the animal and vegetable kingdoms. Biology, or the science of life, in the individual merges into Sociology, or the science of life among an aggregation of social units, that is, society—and the same laws that govern two kindred sciences just as truly control the development of the mental organism. From the old tribal chief, with his exhortations, we have gradually come, through manuscripts, to the age of printing. Newspapers and books have followed in due order, and if we watch the present spirit of activity in the literary world, we see that there has been a still further unfolding, particularly in our own profession. Less books, perhaps, are written by our best men, that is, books covering a wide range of topics. More is done in the line of monographs or in the presentation of papers before society gatherings.

After all, is not this but another manifestation of that tendency to specialism so prevalent among medical men? It seems to us so to be. Moreover, it happily is free from many of those features which in the specialization of medical practice have given rise to so much acrimony. Many and sometimes bitter have been the wordy wars between the general and the special practitioner of medicine. We took occasion to remark some months ago that the latter would appear just in proportion to the demand for them. They are a product of the call of the times for division of labor, and the number of true specialists will be regulated, as are all inorganic commodities, by the law of supply and demand.

We see, then, that the best thoughts of the profession are more likely to be promulgated in the form of papers than ever before. This has both encouraging and discouraging features. There is encouragement in the fact that many who would shrink from the task of writing a set treatise, will, from their garnered wisdom, enlighten us on topics concerning which they are particularly well qualified to judge. There is discouragement in the fact that the preparation of a paper seems such a slight task, comparatively, that we may be flooded with a series of contributions, shallow, indecisive, and not contributing anything to our positive knowledge.

No paper, then, should be a mere repetition of what has preceded it! If it contain the results of original investigation on any topic, it is worthy of being read. Its value varies with the experience of its writer, the carefulness of his experiments, and the logic of his deductions. It is worthy also of presentation if it contains observations on any new topic or new phase of an old topic. From all these communications the future treatises on medicine will derive useful information. We cannot, as a rule, rightly record the history of our own times. We are too much a part and parcel of it to have the unbiassed judgment of the historian. The present prolific literature on our Civil War is showing us the falsity of many of the conclusions of a score of years ago. The present discussion on many of the problems of pathology, while unsettling to our own opinions, is yet the prerequisite for the solidification of truth. Right here is the province of the carefully written paper: it feeds the discussion with facts. Our system of therapeutics, around which all other branches of medicine centre, must be constructed by the inductive method. We must reason from a part to the whole. From authentic facts we must infer the general law which governs them.

THE HAIR-ROOTS AS INDICATORS OF BODILY OR MENTAL DISEASE.

Some time ago considerable notoriety was given to a claim that changes in bodily health could be detected by an examination of the white blood-cells, or, again, by a study of the hæmatoblasts and the mode of blood-coagulation. Something much more unique and apparently fantastic has been announced by Dr. J. Pohl-Pincus, of Berlin. This investigator, in a brochure entitled "Polarized Light as a Means of Recognizing Irritable Conditions of the Nerves of the Scalp," claims that by an examination of the hair-roots by polarized light peculiar changes may be observed whenever the patient suffers from physical irritation or mental excitement.

Dr. Pohl-Pincus rushes forward with no hasty conclusions, but says that his investigations have now been going on for twenty-five years, and that his later observations continue to confirm those made earlier.

If, in healthy conditions of the body and mind, the hairs that fall out daily are examined microscopically by polarized light, the enlarged bulbous end of the root will show a white contour and a yellowish, or brownish-red, centre (Form A).

In all irritable conditions of moderate grade, all painful conditions of any organ, also in emotional disturbances of moderate grade without any apparent bodily disease, the bulbous end of the hair-root increases in length and breadth (in proportion to the intensity of the irritation), the central part appears under polarized light of a violet, blue, or bluish-green color, separated from the white contour by bands of yellow and red (Form B).

In higher grades of bodily disease or mental disturbance the bulb becomes still larger, and the bluish centre changes to green, yellow, or orange (Form C).

A few hairs of the B and C type are found in normal conditions, especially in those more advanced in life.

A professor of jurisprudence, aged forty-six, suffered from overwork and great mental anxiety. Fifty-seven fallen hairs showed: of Form A, 11; Form B, 24; Form C, 23. Two years later, when in good health and free from worry, 34 fallen hairs were classed as follows: Form A, 18; Form B, 16; Form C, 0.

A young man, aged nineteen, while studying for examination, had in 38 hairs: Form A, 16; Form B, 19; Form C, 3. Three weeks later, while at examinations: Form A, 7; Form B, 12; Form C, 17.

Thirty-one cases, showing the effects of painful disease, but more especially of depressing emotions upon the appearance of the hair-roots, are reported.

Dr. Pincus concludes that bodily disease or mental excitement causes circulatory disturbances, and in consequence a change in the normal nutrition and pigmentation of the hair. This is only in accordance with previous observation, and it appears that the merit of Dr. Pincus' discovery, if such it is, lies in his obtaining a means by which very slight and temporary changes in tissue-growth can be detected and approximately measured.

MEDICAL ADVERTISEMENTS IN NEWSPAPERS AGAIN.

Instances of medical advertising have of late been so numerous and flagrant, and the practice is so liable seriously to hurt the profession in every way, that we have not hesitated to criticise the perpetrators sharply. In this we are doing only what the sentiment of the profession as well as its material interests and dignity demand.

To those bold enough to say that there is nothing immoral in public advertising, we answer at once that they are mistaken, because whatever tends to injure our fellows is wrong; and if, of two equally good physicians, one advertises and the other does not, the latter's reputation and practice may be seriously thrown into the shade. If we as a profession should ever be driven to the position that all must advertise, then medicine loses its dignity as a calling, and has an expensive and often dishonest encumbrance added to it.

We can hardly make this plea for preserving the traditional methods of our calling without an apology for so doing. Having made it, however, we would add that, perhaps in one case out of ten of the newspaper advertisements, the doctor is not at fault. One such case apparently occurred at Auburn, N. Y., recently. We criticised severely the announcement in flaming sentences of a surgical operation done by a physician of that city. We learn from authentic sources that the doctor in question had nothing to do with the publication of the article, but that it was communicated to a reporter by the patient himself, without the knowledge of the surgeon. It is needless to say that we are extremely glad to learn and to announce that these are the real facts in the case.

THE CARTWRIGHT LECTURES ON THE BLOOD-PLAQUE.

Dr. Osler's opening lecture upon "The Blood-Plaque" was an interesting one, and gave promise that the present Cartwright series will furnish some solid contribution to medical science. The lecture was devoted entirely to a description of the "third blood-corpuscle." This we are told is identical with the elementary corpuscle of Zimmermann, the hæmatoblasts of Hayem, and the blood-plate of Bizzozero. The so-called "invisible corpuscle" of Norris is a different thing, according to Dr. Osler, although Norris claimed that the corpuscle described by him was the same as that of Bizzozero. The blood-plaque is also identical, presumably, with the *grains sarcodiques* of Vulpian, and the globulins of Donné. Very full accounts of these bodies have been given by Bizzozero and Hayem, and this is not the first time that Dr. Osler himself has contributed to our knowledge of them.

Dr. Osler describes the blood-plaque as a colorless, protoplasmic disk, constant in the blood of mammals, measuring from 1.5 to 3.5 micro-millimetres. The number varies at different periods of life and in disease. In a healthy adult there are between 200,000 and 300,000 per cubic millimetre of blood. In the same amount of blood there are about 10,000 white and 5,000,000 red blood-cells, so that the ratios would be about 500 red cells to 25 blood-plaques and 1 white cell.

Dr. Osler gave an account of the normal and pathological variations in these corpuscles. They are more numerous in the young, and are increased in number in cachectic conditions, as was first noted by Riess; also in the convalescent stage of fevers, but not in the active stage, as Vulpian states. In certain cases of profound anæmia the blood-plaques are very scanty, while in the so-called blood diseases they vary much in number.

The modes of studying this plaque are numerous. Dr. Osler, in 1874, showed that they could be readily seen in the blood-vessels of a young rat by snipping out a piece of the subcutaneous tissue and examining it in a saline solution. It was, we believe, Bizzozero who showed that they could be seen in the circulating blood of the guinea-pig by stretching the mesentery over a ring of cork. They can be well seen also, according to Osler, by allowing the blood to flow directly into a one per cent. solution of osmic acid, or into Pacini's fluid.

The blood-plaques are smooth, homogeneous bits of protoplasm, with no nucleus. They are in the form of a flat circular disk. Seen edgewise they look like rods. There is no certain evidence that they are biconcave. When withdrawn in the blood they very rapidly disintegrate and agglutinate, forming the "granule masses" described by Schultze. They do not undergo amœboid movements.

They have been believed to be very important factors in the process of coagulation. The blood-plaque is constant in the blood of mammals, varying, however, in size. In birds there is a corpuscle which appears to be analogous with the plaque, but it is, according to Dr. Osler, nucleated.

The description of "the third blood-corpuscle," of which we have thus given a brief outline, is not a new one, but the lecturer has made valuable additions to our knowledge of it, and given a better standing to a morphological element heretofore regarded by physiologists with the suspicion always accorded to scientific strangers.

Cholera in Japan.—The epidemic which prevailed in Japan during 1885 was recognized as cholera at Nagasaka, August 23d. The disease next made its appearance in Kumamoto. In Hiogo one case occurred on board an American man-of-war recently from Nagasaka. During September and October, cholera prevailed in many places. Reports of cases and deaths have, however, not yet been received. Forty-five counties, embracing an area of 5,600 square miles, are reported as having been infected. Cholera last prevailed in Japan in 1882.—*Bulletin of Nat. Board of Health*.

Death at an Advanced Age.—According to the Russian journal *Kaspii*, a woman recently died in the Province of Baku aged one hundred and thirty. Careful statisticians have claimed that there is no authentic instance of anyone living beyond the age of one hundred and ten.

News of the Week.

THE WILL OF DR. FLINT.—By the provisions of his will, Dr. Flint gives his medical library to the New York Academy of Medicine, with the exception of such works as the family may wish to retain.

BLOOMINGDALE ASYLUM.—It is proposed to tax the Bloomingdale Asylum, and to open streets through its property. The managers naturally object to this and claim that the money saved by the freedom from taxation goes to lessen the cost of treatment, and is really applied in charity. It appears that the only point on which the managers case is weak is this: that they have no right to ask the citizens of New York City to be taxed for the support of an institution whose charities, such as they are, are not limited to the residents of New York City.

THE CONGRESS: FIGHTING OR COMPROMISING.—Everyone is liable to error, although if there are ever exceptions it is the editorial staff of a medical journal. With this proviso we must repeat our statement that the affairs of the next International Congress are not in a promising condition. There is apathy and discord at home, a state of doubtfulness and expectancy, to put it mildly, abroad. It is utterly useless to deny this, and it appears to us most unwise for certain of our esteemed contemporaries to close their eyes and blindly shout that all is well. All is not well, and no amount of strident vocalization can make it so. The death of Dr. Flint and the illness of Dr. Davis are additional blows to those who appear to wish to rule the Congress on an association basis, or ruin it. We urge attempts at peace and compromise at the St. Louis meeting. There must be some compromises or the Congress will have to meet while antagonizing a considerable and influential part of the medical profession in this country.

THE FAILURE OF MEDICAL LEGISLATION IN MARYLAND.—The *Maryland Medical Journal* states that the bill to regulate the practice of medicine in Maryland, now before the Legislature, was drawn up and at first approved by the Medical and Chirurgical Faculty of the State. The bill was modelled on that of Illinois, and provided for an examining board of five regular physicians and two homœopaths. On subsequent maturer consideration, the Faculty decided to withdraw its approbation from the bill. The *Maryland Medical Journal* says that no law can be had without some concession to homœopathy.

PROFESSOR BILLROTH has gone to Egypt on account of his health.

ANOTHER DEATH AMONG PASTEUR'S PATIENTS.—Nineteen Russian mujiks, who had all been bitten by mad wolves, arrived in Paris on March 15th, and were at once placed under M. Pasteur's care. Inoculations were at once begun and were made twice daily. On March 22d, *i.e.*, on the seventh day, one of the patients was attacked with hydrophobia and died in great agony. The symptoms of the attack came on on the fifth day, after the mujik had been inoculated over half a dozen times, from an infected cord only about seven days old. The other patients are reported as doing well.

NEW YORK HOSPITAL.—Mr. Joseph Pulitzer has given his first year's salary as Congressman, $5,000, to the New York Hospital, to found a free bed for the benefit of newspaper men.

A NEW CURE FOR CONSUMPTION.—Dr. Caius, some four hundred years ago, when an old man, tried to regain his youth by suckling the breast of a woman. He died of stone—not of old age, at least. A more successful application of this remedy is reported to us by a correspondent, who says that "a party who had every indication of the last stages of consumption has regained former health, and attributes it to obtaining his nourishment from sucking a healthy nursing woman."

CHOLERA IN EUROPE.—Our reports cover the three weeks, December 23d to January 15th, at which date cholera was still prevalent in the Department of Finisterre, France. December 23d to 30th, there were 73 cases and 14 deaths; December 31st to January 7th, 74 cases and 7 deaths, and from January 8th to 15th, 55 cases and 11 deaths.—*Bulletin Nat. Board of Health.*

CHOLERA IN AUSTRALIA.—Four deaths from cholera occurred at Sydney in December, 1885.

A DENTAL SCHOOL IN VIENNA.—The Professorial Senate in Vienna have under discussion the question of establishing a dental school in connection with the medical faculty.

THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NASHVILLE graduated a class of ninety-six at its commencement on February 25th.

DR. HARVEY D. BURLINGHAM, of Plainfield, N. J., died at his residence there on March 17th, aged fifty-four. He graduated in 1857 from the College of Physicians and Surgeons, in New York, and served in the United States Navy as a surgeon during the late war. He became a resident of Plainfield in 1872.

DR. J. S. KNIGHT, Surgeon United States Navy, died suddenly of heart disease, at Hyannis, Mass., on Sunday last. Dr. Knight was born in Delaware, entered the service in 1861 as assistant surgeon, and was commissioned as surgeon in 1866.

DR. JOHN K. KANE, one of the leading practitioners of Delaware, died recently at Summit, N. J. Dr. Kane was born in Philadelphia, December 18, 1833. He studied medicine at Jefferson Medical College, Philadelphia, and at one of the medical schools in Paris, and settled in Wilmington for the practice of his profession. His brothers were General Thomas L. Kane, who went into the late war as colonel of the celebrated Bucktail Regiment of Pennsylvania, and Elisha Kent Kane, the Arctic explorer. Dr. John K. Kane accompanied the expedition which went to the northern seas in 1856 for the relief of his brother, and was one of the surgeons.

CARING FOR NEW JERSEY'S INSANE.—The commissioners of the Morris Plains Asylum presented to the legislative committee yesterday plans for a sewerage system for the institution. The contemplated expense is $30,000, and the Legislature is to be asked to make an appropriation of that sum. Dr. E. E. Smith, the medical director of the institution, has tendered his resignation, to take effect on June 1st.

Poisonous Wall-papers.—A bill has been submitted to the Massachusetts Legislature prohibiting the manufacture and sale of wall-papers containing more than one-fourth of a grain of arsenic to the square yard, and permitting the sale of such papers containing not more than one-fourth grain to the square yard. Dr. Edward S. Wood claims that arsenic is sometimes put into paste to prevent its souring. It seems that a law permitting the use of arsenic to the extent of one-half grain to the square yard, as required by English law, would answer the case. In Germany, Sweden, and Bavaria the law forbids the sale of arsenical wall-papers.

A Proposition to Establish a Post-graduate School in London is being agitated.

A Pasteur Institute.—A commission appointed by the Academy of Sciences has decided upon the establishment of a *locale* in Paris for the treatment of persons bitten by mad dogs. It is to be called "Institut Pasteur," and is to be supported by public subscription. As it is intended to be international, subscriptions are solicited from all parts of the world. A cable despatch announces that already about $10,000 has been raised.

The Efficacy of Vaccination.—The New York State Board of Health announces that it was successful in preventing the introduction of small-pox from Montreal last fall, and that its work signally demonstrated the utility of vaccination and the activity of the New York City Board of Health virus.

Dr. Bochefontaine, chief of the Laboratory of the Faculty of Medicine of Paris, died recently. He was an active opponent of the microbic theories of Pasteur and Koch, and swallowed a dose of cholera bacilli during the epidemic last year in order to prove their innocuousness.

Dr. Chr. Bohr succeeds the late Professor Panum as Professor of Physiology at Copenhagen.

Not Favoring Pasteur.—The Vienna city government has refused to accept the proposal of Princess Metternich to send medical men to Paris to learn Pasteur's method of preventing hydrophobia

Hopeine is a substance which is claimed to be the alkaloid of hops. Whether there is such a thing is yet a question. It is stated that several samples of English hopeine examined were found to be really only impure morphine. On the other hand, the *Pharmaceutical Journal*, of London, claims that the alkaloid has been obtained, and is now being tested.

Against Cremation.—Dr. Frank H. Hamilton's paper, entitled "Cremation not Required as a Sanitary Measure," has deservedly received wide notice. It should put a quietus on a great deal of foolish talk about the dangers of inhumation.

A State Hospital for Virginia.—A Richmond paper says: "The medical fraternity are moving in the matter of securing from the Legislature an appropriation of $12,000 a year, for the maintenance of a State hospital to be located in Richmond. Without going into the full details of the scheme, as set forth in a bill now before us, we would say that the main object is to furnish "treatment for indigent persons from the State of Virginia who are suffering from curable but non-contagious diseases and injuries."

Small-Pox in Italy continues to increase. During December there were 2,679 cases, distributed in 153 localities.

A College of Pharmacy is to be established at Buffalo, in connection with the medical department of the University. Professor R. A. Witthaus has been elected President of the faculty.

Tying the Lingual Artery with the Eyes Closed.—Billroth has recently done several operations for cancer of the tongue. A correspondent of the *Iowa State Medical Reporter* says: "The operation, by tying the lingual artery, was nearly bloodless. In order to show the students how easy it was to tie the lingual artery, he found and ligated the same in one case, after making the first incision, without using his eyes."

The Cook County Insane Asylum.—Investigation has shown that the management of this institution, since its foundation, thirty years ago, has been unspeakably bad. It has been a part of the political machine, and care of the "boys" has been considered first, the care of the insane last. It is recommended that the institution as such be abolished, and the insane inmates be placed under the care of the State. Nothing in the history of local government in this country shows more clearly the pernicious results of the political machine system applied to medical charities.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 22, 1886.

Daniel Lewis, M.D., President, in the Chair.

Dr. L. D. Bulkley read a paper on

THE RELATIONS BETWEEN DISEASE OF THE SKIN AND DISORDERS OF OTHER ORGANS.

The skin may become idiopathically affected the same as any other organ, but local pathology has been carried so far by some as almost to ignore the existence of any relationship between diseases of the skin and the conditions of other organs.

The author of the paper read a letter received from a patient who gave an exceedingly intelligent account of her symptoms, associated with acne, rosacea, eczema, and bromidrosis; these were referable to the digestive organs, such as constipation or diarrhœa, more or less nausea, restlessness, etc., retarded menstruation, occasional attacks of severe pain in the head. Such a diversity of symptoms would almost instinctively lead one to treat the patient by other than local measures.

The subject proper of the paper was studied under the following heads: The relation which exists between diseases of the skin and (1) the digestive organs; (2) nervous disorders; (3) circulatory disorders; (4) sexual disorders; (5) general conditions, as anæmia and debility; (6) special conditions, as malaria, gout, and rheumatism.

The general conclusion of the paper was that diseases of the skin may sometimes bear important relations to other organs, and he will act most wisely in endeavoring to remedy the former who considers the whole of the individual presenting the same, and he will succeed

best who most fully recognizes and appreciates the relations which the skin and the other organs sustain to each other.

Dr. C. Heitzman had scarcely anything to criticise in Dr. Bulkley's paper, although educated in the Vienna school, which teaches that many of the skin diseases are purely local, yet a great many of them do depend upon internal diseases. Dr. Heitzman agreed with Dr. Bulkley that the parasitic skin diseases, such as tinea tonsurans, etc., are local, although some dermatologists regard them as constitutional. Urticaria, also, may depend upon disturbances of digestion, may occur independently of such disorders, and may be caused by uterine troubles. That skin diseases frequently depend upon disorders of the nervous system was very obvious.

Dr. George T. Jackson referred to the doctrines of the French and German schools, and said he believed that the middle course was the best to pursue, namely—that skin diseases may be either local or constitutional.

Dr. J. Leonard Corning spoke of the relation between skin lesions and nervous affections, and thought that we should know more of this relation as pathology advanced.

Dr. C. W. Allen believed that in very many cases the skin must present a suitable soil for the parasite to develop before the person would have such affections as favus, etc. The cause of local lesions was sometimes very near at hand, as in the case of a cutaneous lesion affecting the upper lip and alæ of the nose, caused by peculiar nasal cartarrh, etc. Diabetes also was a frequent cause of skin lesions, notably pruritus.

Dr. Hadden had seen numerous cases of disorders of the skin dependent upon diabetes, most frequently in the aged. He regarded many skin diseases as having a close relation to constitutional conditions, and addressed his treatment at first to the correction of these errors.

Dr. Bulkley in closing the discussion said that he did not wish to be understood as saying that urticaria always depended upon digestive disorders, for it also depends upon nervous disorders very frequently, etc. He believed that favus, or ring-worm, did not develop in healthy individuals, and that to treat such parasitic affections most successfully internal medication was required, such as tonics, alteratives, alkalies, etc.

Dr. Stephen Smith then read a paper on

THE EFFECTS OF HIGH TEMPERATURE ON THE PUBLIC HEALTH OF THE CITY, AND THE MEASURES FOR THEIR PREVENTION,

in which he pointed out the effect on the rate of mortality produced by the high temperature of the summer months, especially July, August, and September; also the conditions which favored an increase in mortality under the influence of high temperature, as age, rest, and activity, the introduction into the blood of decomposing animal matter, etc. The special causes of high temperature in the city of New York were Southern exposure, absence of vegetation, aggregation of stone, brick, and mortar, and crowded population. The measures for the prevention of the deleterious effects of high temperature were: moderation of the temperature of the atmosphere by means of shade-trees, and flushing the streets with water, and the daily regulating and equalizing of bodily temperature by artificial means, such as public baths.

Dr. Smith also read a bill entitled: "An Act to Secure the Increase and Protection of Shade-trees in the Streets, Avenues, Public Squares and Spaces in the City of New York," which had been prepared with the view to Legislative enactment, for the purpose of providing the city with shade-trees, and asked that it be referred to the Committee on Hygiene with the approval of the Society.

Dr. Bulkley moved to amend by including additional water-supply for flushing the streets, and it was so ordered.

Remarks were made by Drs. Peters, Carpenter, Hadden, and others, and the subject was referred to the Committee on Hygiene, with power to act for the Society, with reference to the indorsement of the proposed measure.

The President made the following

ANNOUNCEMENT OF THE DEATH OF THREE MEMBERS.

"It is my sad duty to announce the death of three members of this Society since the meeting four weeks ago. Such a record of mortality in our ranks is remarkable in several respects, for which reason I hope you will indulge my brief reference to it.

"Never, so far as can be learned, has so large a number been transferred from our midst in so brief a period. Four weeks ago to-night, they were all in the midst of their active professional labors. To-night every earthly thought, ambition, motive, and plan of those three lives is ended forever. Such a sudden stroke is an unusual reminder of the uncertainties surrounding all that relates to human life. It is also worthy of remark that all three were prominently identified with the medical history of the present day.

"Dr. Gaspar Griswold, who died after four days' illness, had not reached thirty years of age, and yet was well and favorably known as a teacher and medical writer. His future bid fair to be one of uncommon usefulness and brilliancy.

"Dr. Austin Flint was recognized in both hemispheres as one of the best of medical instructors. Flint's 'Practice of Medicine' is the best book ever written on that subject for medical students. His name and his fame will ever remain one of the brightest pages of American medical history. None who knew him personally can forget his characteristic geniality of manner and absolute purity of life, which made him a medical gentleman in the best sense of the term. No one can be found to fill his place.

"Dr. S. Oakley VanderPoel, my immediate predecessor in the chair, can receive no encomium from us which will more than equal the distinguished position he attained as an earnest, independent, conscientious man, whose wonderful energy and ability as an executive placed him in the front rank of the profession. It was fortunate for a young physician to know Dr. VanderPoel, for he had the power of impressing upon his associates, to an unusual degree, his own sterling qualities. The County Society has lost an ex-president whose name was one of its ornaments, and whose wise counsels it is hoped may not soon be forgotten.

"Dr. Agnew has kindly consented to present a memoir of his life at a future meeting; Dr. Carpenter will be memorialist for Dr. Flint, and a like announcement for Dr. Griswold will be made at the next meeting of the Society."

The Society then adjourned.

A Substitute for Cantharides.—A Spanish beetle, *Œnas afer*, has been found by Dr. Armengue, of Barcelona, to possess a vesicating principle which can be extracted and made use of like cantharides, over which it is stated to have the advantages of greater cheapness, absence of irritating effects on the kidneys and reproductive organs, and last, but not least, of entire painlessness.

Anæsthesia by Ether Vapor.—Dr. A. F. Muller (*Medical News*) reports excellent results for securing a steady flow of ether vapor to the patient. He has an apparatus consisting of two halves of a rubber foot-ball, sewed together at the edges, and connected by a tube with a bottle containing ether, which is plunged in a vessel of hot water. As ether boils at 98°, the vapor passes steadily and rapidly, and is inhaled by the patient, whose face is covered by the inhaler, protected by a clean towel. There is no nausea, no struggling, no stage of excitement. The quantity of ether varies from an ounce and a half to three ounces.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 18, 1886.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE Corresponding Secretary reported the death of Samuel Oakley VanderPoel, M.D., LL.D., Honorary and Resident Fellow; of Austin Flint, M.D., LL.D., ex-President, and, in the absence of the Statistical Secretary, of Gaspar Griswold, M.D., M.R.C.S.

The President appointed Stephen Smith, M.D., memorialist for Alfred C. Post, M.D., LL.D., and said that he should claim for himself the honor of memorialist for their distinguished ex-President, Austin Flint. Memorialists for Dr. VanderPoel and Dr. Griswold will be appointed at the next meeting of the Academy.

THE SIGNIFICANCE OF SMALL QUANTITIES OF SUGAR IN THE URINE.

The discussion on this subject was under the auspices of the Section in Theory and Practice of Medicine, Alfred L. Loomis, M.D., LL.D., Chairman, and was opened by Dr. THOMAS A. MCBRIDE, who said that he first had his attention especially directed to the significance of small quantities of sugar in the urine by Seegen, of Vienna, and that, by the adoption of therapeutic measures intended to correct this abnormal condition, he could assure this class of patients that they would be benefited, at least, and almost always be cured.

A large number of affections exhibit sugar in the urine some time during their course, and, of disturbances referable to the nervous system, cerebral hemorrhage, fracture of the skull, concussion of the brain, and certain psychoses; and in the latter particularly, the sugar is believed to exercise an important influence in the production of the symptoms of which the patient complains. Sugar may be present in the urine in certain cases of lithæmia. Dr. McBride had found sugar in the urine of persons suffering from insomnia, restlessness, and general nervousness, neurasthenia, parasthesia, general and symmetrical or asymmetrical, in hemiparæsthesia, and also in certain pareses. In two cases it was evidently the cause of temporary hemiplegia. In all these cases the ordinary tests for sugar in the urine were employed, and in many of them with negative results; but by Seegen's method the presence of sugar was demonstrated distinctly.

The method consists in filtering the urine through *blood* (not animal) charcoal (most reliable imported by Fraser & Co.), then washing the filter with distilled water, afterward testing the second, third, and fourth *washings* with Fehling's solution. From $\frac{1}{10}$ to $\frac{1}{2}$ per cent. of sugar may not be detected by the ordinary use of the Fehling test.

His treatment had consisted in regulating the diet, and the internal use of arsenic, more particularly Clemens' solution, the arsenite of bromine.

Just at present he was at a loss to say what is, and what is, not diabetes.

DR. KINNICUTT said that several years ago Lauder Brunton called attention to the fact that, occasionally, on the addition of sulphate of copper and caustic potash, or of Pavy's solution, to diabetic urine, a precipitation of the oxide of copper did not occur. He believed that it was due to the presence of some other substance in the urine, which kept the reduced oxide of copper in solution. He found that, by largely diluting such urines and so lessening the solvent power of this substance, whatever it might be, the precipitation of the oxide took place. He also had noticed that this peculiarity in reaction most commonly was present in urines which give a purple coloration on the addition of nitric acid. Kühne long ago called attention to the fact that in normal urine, to which was added as much as one-half to one per cent. of sugar, a reduction of cuprous oxide failed to occur. Normal urine, therefore, probably contains the substance or substances which prevent the precipitation of the oxide of copper.

These facts would suggest the usefulness of the method described by Dr. McBride.

DR. R. C. M. PAGE said that glycosuria could be conveniently divided into three classes of cases: 1, that occurring after the ingestion of an excess of sugar; 2, that in which sugar is present in large quantity, but not continuous; and 3, that in which sugar is present in small or variable quantity, but persistent.

According to Niemeyer, diabetes occurs most frequently in men, and between the ages of thirty and forty years; but his experience had been that it occurs most frequently in women, and after the middle period of life; and that such cases are usually mild and intermittent. So far as treatment was concerned, he had no faith in the efficacy of drugs. Beyond affording rest, he did not regard opium as beneficial.

DR. GEORGE P. FOWLER gave an outline of the experiments and observations which led him to the conclusion that sugar, in slight trace or marked quantity, will come into the urine after being taken into an empty stomach. When, therefore, a patient comes to him with sugar in the urine, low specific gravity, and the symptoms not very severe, he immediately sets himself to work to ascertain whether or not sugar, saccharine fruit, etc., has not been partaken of freely, and whether or not there is anything wrong in the process through which sugar passes to become properly digested.

DR. W. H. DRAPER had ceased to attach very much importance to the occasional presence of very small quantities of sugar in the urine, for the reason so well stated by Dr. Fowler. He had found it very often in connection with the condition known as lithæmia; that is to say, with a variety of dyspepsia in which there is evidence in the urine of suboxidation. He had been accustomed to regard sugar in the urine, as he did an excess of urates, as an indication of defective conversion of the food elements. He had also found that the treatment which caused the disappearance of the urates also caused the disappearance of the sugar. He believed that there was a great deal of truth in Dr. McBride's statement, that he was unable to say exactly where diabetes begins. Dr. Draper thought that, frequently, the mild form of diabetes was nothing more than a form of indigestion; the grave form, the true diabetes mellitus, being that in which sugar is formed from azotized food.

DR. MCBRIDE said he had found sugar, as he supposed, in the urine of lithæmics, but when the fermentation test and the polariscope were used he had ascertained that sugar was not present.

Sugar, when present *persistently* in small quantities in the urine, seemed to indicate excess of sugar in the blood. It had been claimed by Seegen that when more than one-tenth per cent. was in the blood, it could be found in the urine, and that in this quantity it acts as an irritant to the nervous centres and produces certain nervous phenomena. Furthermore, it had occurred to Dr. McBride that the sugar might not be of the variety almost always appreciated by the ordinary tests when the urine is diluted, but perhaps is of the variety found in the muscles.

DR. DRAPER said he was well aware that uric acid occasionally gave a reduction of the oxide of copper in the use of Fehling's solution, but he had frequently verified the presence of sugar in such cases as he had described. As to the nervous symptoms due to the persistent presence of sugar in the urine, he thought it impossible to distinguish these from the symptoms which occur in cases of lithæmia in which sugar is not found in the urine.

Dr. Draper believed that gout and diabetes were closely allied, and that both were frequently found under the same conditions in which lithæmia occurred.

DR. MCBRIDE agreed with Dr. Draper, except that he thought that sugar could produce certain nervous symptoms, the same as uric acid does, and other poisons circulating in the system.

Dr. Devlin had recently seen the statement that the inhalation of nitrous oxide gas was likely to be followed by sugar in the urine, and asked if the Fellows had any experience to relate on this point.

Dr. Hudson had observed sugar in the urine after the inhalation of chloroform, but he thought that it was not of special significance.

The President said that sugar was present in the urine of a great many persons at different times without meaning much; that is, small quantities recognized by Fehling's test. Such patients may be in tolerably fair health for ten, fifteen, or twenty years or more. As a rule, such persons are under thirty years of age; rarely from forty to sixty. Not all of these are mild cases; a large number of them live for a long time; some get well. The diabetic symptoms are likely to be intermittent. Some of these patients are gouty. Under treatment, dietetic and medicinal, they get well temporarily. When such persons, however, get sick with any acute disease, especially pulmonary, they are in very great danger. Thus small quantities of sugar in the urine may mean much, or they may mean but little.

THE TREATMENT OF DIABETES.

The discussion on this part of the subject was opened by Dr. F. A. Burrall, who spoke of treatment under three heads: the dietetic, the hygienic, and the medicinal. According to Donkin, clinical experience favors the use of pure milk as the main article of diet. Glycerine is of doubtful propriety. Individual peculiarities must be considered. No exclusive plan can be given.

Dr. C. M. Cauldwell spoke of the use of jambol, which he had administered with benefit in three or four cases, and to these he could add two cases under the care of Drs. Keyes and Alexander, one of which was benefited and the other not. Probably the success in these six cases was due in a large measure to dietetic and hygienic treatment.

Dr. W. H. Draper continued the discussion and said that, excluding the dietetic treatment of diabetes, it may be truly stated that our treatment of the disease is as purely empirical as our knowledge of its pathology is speculative. This must needs be so, for until we know the determining cause of the malassimilation, which is the essential feature of the disease, we cannot expect to have any rational basis for its treatment. It is a curious fact in the history of the medicinal treatment of diabetes that we have little experience of the value of any drug independently of concurrent dietetic management. I think I may truly say that we have no testimony that drugs alone, without the more or less exclusion of starchy and saccharine foods, can check the malassimilation of glycerine in the diabetic.

While I believe that certain drugs are of service in controlling glycosuria, my experience leads me more and more toward the conviction that dietetic and hygienic means are, after all, the essential factors in the successful management of this disease.

In estimating the value of any medicinal treatment we are apt to be led astray, not only by the fact that careful exclusion of the carbohydrates is generally insisted upon, but also by the fact that many cases, perhaps the larger proportion, are cases of what has been called the benign form of the disease—cases in which the disease seems to consist simply of a loss of power to convert the food-sugars, the sugars and starches. Such cases are apt to occur in persons past middle life, with a history of acquired or hereditary gout, with a tendency to obesity, and stout persons and heavy feeders upon sweets and farinaceous stuffs. These are the cases which are often intermittent, which get well, or almost well, and remain so upon an appropriate diet and good hygienic conditions. But the grave cases, those in which glycogen is formed from the nitrogenous foods, and in which the exclusion of the carbohydrates serves only to diminish the degree of the glycosuria—cases generally occurring in persons who have received some serious nervous shock, or in whom there are evidences of tissue-degeneration—these are the cases on which to test the efficacy of drugs, and they are the cases which thus far, unhappily, are not cured, though they are often ameliorated, by the use of medicines.

The drugs upon which I am accustomed to rely in the treatment of diabetes are opium—generally in the form of codeia—the sulphide of calcium, and the alkaline carbonates. It cannot be said that the rationale of the action of any of these drugs is understood. It seems probable that opium acts through the vaso-motor nerves; but how, whether it stimulates metabolism, or in some mysterious way regulates it, it is vain to ask. It certainly is a great boon to the diabetic, and in connection with a more or less modified diet, it may cure, and it is pretty certain to control his disease. The treatment by sulphide of calcium was introduced by Dr. Husted, formerly of this city, now of Tarrytown. He was led to use it on himself by its being vaunted as a remedy for furuncles—a complication of diabetes from which he was at the time suffering. To his surprise and satisfaction he found that it not only cured his boils, but caused the sugar to disappear from his urine. Dr. Husted remains well, and is able to live in the country upon a simple, mixed diet without glycosuria. I have had considerable experience with the sulphide of calcium. I give it in $\frac{1}{4}$ and $\frac{1}{3}$ grain doses, before meals, three or four times in the twenty-four hours, and in cases of the milder forms of the disease, and especially in those having a gouty history, with good result. I have never used it without some modification of the diet, but I believe that it enables the patient to enjoy more freedom in diet than he could without it.

The alkaline carbonates have been in my hands most useful remedies. It was stated by Miahle that they were a specific for diabetes, and it is doubtless to these substances that the springs which are renowned in the treatment of this disease owe their reputation.

The theory of Miahle, that they promote oxidation, is one that is based upon the chemical theory that diabetes is a disease of suboxidation. The frequent association of diabetes with gout in different members of the same family, and frequently in the same individual, and the value of alkalies in the treatment of both these disorders, are certainly striking facts, and they seem to lend some plausibility to the hypothesis that the defective metabolism in diabetes and gout is really due to a defective oxidation, and that perhaps the nearest approach to a rational treatment of both these diseases is an effort, through hygienic and medicinal means, to stimulate oxidation.

Dr. Dadirrian spoke of the treatment of diabetes practised in Constantinople. The dietetic management consisted chiefly in the use of fermented cow's milk, also used by the Germans, the French, and the English, differing from ordinary milk only in the fact that it does not contain sugar. It is called matzoon, and he had prepared it and used it, not only there but here, with good success as an article of diet.

Dr. Dawbarn spoke concerning Merck's preparation, as being the only reliable one of sulphide of calcium.

Dr. R. F. Weir spoke of the occurrence of gangrene in cases of diabetes, and referred to one case in which some of the peripheral portions of one upper extremity were involved, and in which he amputated and the patient recovered. In a second case, occurring in the lower extremity, the patient died. In a third case, the patient recovered from an attack of pneumonia, and twelve days afterward gangrene developed in one of the lower extremities and the question of amputation through the thigh arose. He found nine cases reported of amputation of the thigh for gangrene below the knee occurring in the course of diabetes, and in only one did recovery take place; in five, death occurred from shock, and in three from coma.

From this account of the success of amputation, he

deemed it best not to perform the operation, and the result showed the wisdom of the decision, because the gangrene spread, a line of demarcation did not form, and the patient died. He asked for the experience of the Fellows on this point.

Dr. Baruch spoke of the benefit of muscular exercise and massage in the treatment of diabetes.

Dr. Draper thought it very dangerous to make those suffering from the severe form of diabetes take very much exercise, especially when the nervous symptoms are prominent. In ordinary cases, exercise in the open air within the limits of fatigue is important and necessary, but fatigue in the severe form is very dangerous.

Dr. Baruch admitted the danger of over-exercise; but at the same time, with the patients' disposition to take as little exercise as possible, exercise is beneficial; but it must be regulated by the judgment of the physician.

Dr. Kinnicutt said that he was wholly in accord with Dr. Draper in regard to the danger to diabetics of overfatigue. Pavy had noticed that diabetic coma not unfrequently was developed in patients shortly after their arrival in London from long railway journeys.

Dr. Kinnicutt had seen during the past two years three cases of diabetic coma in children develop shortly after admission to hospital. He had believed at the time that the fatigue and excitement incident to admission had acted as an exciting cause in its production.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, March 10, 1886.

Alfred L. Loomis, M.D., LL.D., Chairman.

Dr. A. Jacobi read a paper, including practical remarks.

ON THE USE OF DIGITALIS,

based on the experience of a third of a century. The general nature of digitalis and the effects produced by it were well known to all, and needed no special mention. The cardiac symptoms requiring the use of digitalis were irregular and frequent pulse, passive congestion of the pulmonary circulation with secondary bronchial catarrh, small arterial wave, cyanotic surface, coolness of the skin, sensation of chilliness, loss of nutrition, cutaneous œdema, and diminished micturition.

The effect produced by the drug in such cases was first described by Withering, one hundred and thirty years ago, who regarded digitalis as a sedative. To Traube is due the credit of proving that digitalis is a stimulant to the heart and blood-vessels.

Digitalis, with or without iron and nux vomica, acts admirably in cases of fatty heart.

In acute and chronic pulmonary consumption it is a valuable adjuvant to such remedies as arsenic, iron, etc. Repeating what Withering had said more than a century and a quarter ago, he knew of nothing which regulated so well the pulmonary circulation in phthisis as digitalis, which manifested itself by increased regularity of the pulse, etc., and digestive disturbances were not a contra-indication, since they so frequently depended upon venous stasis. In general the dyspepsia of pulmonary affections indicates the use of digitalis.

Anæmia, from almost any cause, is benefited by the use of this drug.

It is not a diuretic in healthy persons; on the contrary, it diminishes the elimination through the kidneys of both water and solid material, and when in such conditions as that of general cachexia it acts as a diuretic, it does so only by increasing arterial pressure.

From experiments on either man or the lower animals no definite conclusions have been reached concerning the exact dose required to produce the best effects.

According to his experience, the following are effective and safe: digitaline, from one-tenth to one-eighth of a grain daily, administered in three doses; extract, from one and a half to two grains, in three or two doses, may be taken, day after day, for one or more weeks. He valued the last preparation very highly, because it can be given in pill form and is easy of combination with other drugs. Digitaline is often inert. Of the leaves, from four to seven grains may be given daily with safety for as many successive days and weeks. The fluid extract had not with him proved so satisfactory as other preparations, and in urgent cases he had resolved not to rely upon it any more than upon digitaline.

Dr. Jacobi then related briefly several cases in which he had prescribed digitalis with advantage. An atheromatous heart and arteries do not bear much digitalis; the muscle is destroyed to a greater or less extent, and therefore cannot be lashed into healthy action; neither in cases of myocarditis does it do well. He had used it with benefit in Graves' disease, combined with other drugs.

Dr. W. H. Thomson was pleased with the paper, because its author had presented the action of digitalis from a clinical rather than from the supposed action derived from physiological experiments. From the literature of the subject he was in a condition of great uncertainty whether digitalis can be prescribed according to physiological data any better than dyspepsia can be treated by physiological rules. The final analysis of digitaline, which has been regarded as the quintessence of digitalis, determines that it contains *five* distinct principles, and opposed in action.

Brunton would by this fact explain the great uncertainty of the preparations of digitalis. For example, in the infusion a good deal of the antagonizing principle is present, and therefore it does not increase the power of the heart's action so much as it produces diuresis; while in the preparations in which alcohol is used as the menstruum those principles which increase the power of the heart's action are present in largest quantity. Furthermore, when we turn to the heart's action, the complexity of the problem is not diminished, for some say that it exerts an inhibitory influence on the vagus, while others claim that it affects the spinal cord, through it the splanchnic, and dilates the arteries of the abdominal viscera, and thus lowers the pressure all over the body; yet others say that it dilates the arterioles, and, lastly, and perhaps as true as any, that its principal action is upon the cardiac muscle itself, without any action upon the nerves at all.

From the physiological point of view, Dr. Thomson was unable to agree with Dr. Jacobi as to the uniformity of the action of digitalis as a cardiac tonic, meaning thereby increase of power of the normal rhythmical cardiac contraction. He had not found it beneficial in the treatment of fatty degeneration of the heart from any cause. No one doubted its efficacy in cases of mitral regurgitation with dilatation. But digitalis is capable of doing harm in many diseases, because it unquestionably increases arterial tension. In Bright's disease with cerebral symptoms he, therefore, would not use it.

In other states it is exceedingly dangerous, as in acute diseases in which, with cardiac fatty degeneration, there is arterial tension, as in certain conditions with diphtheria, etc.

The remedy is undoubtedly beneficial in cases of dyspepsia with abdominal distension, of epistaxis, anæmia, etc., as reported by Dr. Jacobi; and if any comment was to be offered, it would be as to how much was due to the digitalis and how much to the drugs with which it was combined.

Dr. F. A. Castle related two cases which confirmed what Dr. Jacobi had said with reference to the beneficial action of digitalis in cases of fatty heart, and he had also rarely failed to benefit anæmic patients by its administration.

With regard to the activity of the drug, some of the older experiments were made with the leaves, and in many

of them the *digitoxin* practically took no part, because it is insoluble in water. When, therefore, the infusion of digitalis made from the leaves is prescribed, the influence of digitoxin in increasing the power of the heart is not obtained. But if the fluid extract, which is an alcoholic preparation, is used in making the infusion, as many druggists have the habit of doing, digitoxin is administered, and an effect produced different from that obtained by using an infusion of the leaves.

Moreover, the active principles of the leaves are considerably volatile, and he had therefore been accustomed to use the tincture made from the fresh plant.

With reference to the extract spoken of by Dr. Jacobi, it had been ascertained by Dr. Squibb that in preparing it a certain amount of the active principle of the drug is rendered insoluble by the process of desiccation.

Dr. Jacobi said that he intended to speak from the practical point of view. It is agreed that digitalis produces arterial tension, and it is this that is at the bottom of all nutritive changes. Thus it is that the heart itself participates in the improved circulation and general nutrition. The reason why he used digitalis in combination with other drugs was because it was impossible to procure normal circulation without addressing the other organs of the body at the same time. For example, it was essential to keep the bowels regular and the abdominal viscera free from pressure. Thus very frequently, when giving extract of digitalis, he gave it in combination with a purgative; and as much of the circulation in the body depended upon the action of the voluntary muscles, he added nux vomica, which improved the condition of these muscles, and so on.

The topic for general discussion was

THE DIETETIC TREATMENT OF CHRONIC BRIGHT'S DISEASE.

Dr. W. H. Katzenbach opened the discussion by saying that the indications were to maintain and improve nutrition and prevent uræmia, which manifested itself, not only in disturbances of the nervous system, but in flatulence, nausea, vomiting, and frequently diarrhœa. In the selection of articles of diet, therefore, those should be chosen which are easily digested and readily assimilated

He restricted his remarks to the use of milk, which should be taken in quantities varying from three to five pints in twenty-four hours, in equal parts, at intervals of from two to four hours.

The tendency to constipation can be overcome by either, during the first few days, diluting the milk with water, Apollinaris water, or sometimes by the addition of salt, or by peptonizing the milk, or by the use of a seidlitz powder alternating mornings, or some vegetable laxative, after which, as a rule, the bowels will take care of themselves. Illustrative cases were reported.

Dr. Beverley Robinson continued the discussion, and spoke first with reference to the lack of definite directions, in text-books, on the subject under discussion. He thought it exceedingly desirable that more exact data should be obtained, based upon chemical analyses and clinical observations conducted with special reference to quantity of albumin and urea.

He had but little doubt that milk is the best single article of diet, but there were limitations to its use, as, for example, there are some persons who cannot take it, do what you will in way of preparation.

Again, even though albumin and injurious excreta are increased, it is not absolute evidence that harm is being done to the patient, because it is so essential to improve the general nutrition. It seems to be proven, moreover, that the addition of meat to the diet-list does not invariably increase the quantity of albumin excreted by the kidneys.

At St. Luke's Hospital some observations had been made in the direction indicated, and the results had been collected by Dr. E. B. Dench, House Physician. The following is a summary:

"During the last two years 70 cases of chronic Bright's disease have been treated—uncomplicated, 26; complicated, 44.

In the great majority of the cases the diet was milk and farinaceous food. In several cases the addition of farinaceous or nitrogenous food caused a diminution of the urinary secretion for twenty-four hours. In some cases such an addition increased the quantity of albumin in the urine. In one case the quantity of urine was increased by the addition of farinaceous food. The duration of treatment, dietary and medicinal, was from one to three months.

To test roughly the effect of different kinds of dietary treatment on the amount of albumin excreted, Dr. Dench made experiments in three cases. The estimation of the albumin were volumetric; the Doremus test for urea was used.

In Case 1 the milk-diet diminished the amount of albumin, and the addition of farinaceous and light diet (small quantity of meat) caused an increase in the amount of albumin.

In Case 2 there seemed to be no relation between the diet and the quantity of albumin in the urine.

In Case 3 albumin was increased after the addition of meat to the diet, except in one instance, the observations being made for several days.

Dr. Gouverneur M. Smith continued the discussion, and made special reference to a paper which he read before the Academy, April 1, 1869, "On the Etiology of Bright's Disease, with Remarks on the Prophylaxis." The paper was based upon an analysis of 308 cases gathered from the records of the New York Hospital. It seemed to him that many of the points which he then brought before the Academy are as correct as when they were read, and especially with reference to the subject under discussion, for they were based upon well-established physiological facts.

Of the 308 cases, 135 terminated fatally within the hospital, 117 patients were discharged relieved, 14 by request, and in 2 cases the patients became insane. Clinically, the different processes grouped under the term chronic Bright's disease are identical in that the usefulness of glandular structure is impaired, and that the normal functions of the kidneys are to a greater or less extent diminished.

The relations between food and the renal secretion are such that albumin in the urine can be reduced in quantity by cutting off nitrogenized principles and placing the patient on the use of rice or arrow-root, etc. This fact Dr. Smith had observed clinically. It is well known that the water and uric acid can be materially reduced by a proper adjustment of food. Years ago Lehmann proved that urea can be diminished to the minimum by an amylaceous, saccharine, or oleaginous diet. Dalton, Flint, Hammond, and Draper appear to agree that urea is traceable to a disassimilation of the azotized principles of the tissues, and also to a transmutation in the blood of the surplus nitrogenized principles which have been taken as food. The indication, therefore, is, when a patient is menaced with or suffering from uræmia, to cut off essentially nitrogenous food, and to prescribe aliment mainly composed of ternary proximate principles. The necessities of nutrition must always be kept in mind, but with superfluous or inappropriate diet the kidneys cannot receive that rest so evidently required. As diverse causes are operative in the production of chronic renal disease, a specific line of dietetic treatment cannot be laid down as exactly suited to every case, but the quaternary and ternary principles of food can often be handled so skilfully as to checkmate morbid processes.

Dr. Smith said he would venture to repeat what in substance he said in 1869—namely, that in Bright's disease, if the patient is threatened with uræmia, it is a favorable symptom if his urine is heavily loaded with albumin, as thereby a principle is rejected which if retained would directly or indirectly augment the toxæmia.

Such drain of albumin from the blood is, of course, ordinarily pernicious, and the statement just made refers to albuminuria as it occurs under the uræmic conditions alluded to; in some instances it may be beneficial, in others the reverse.

The Section then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 24, 1886.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. G. C. FREEBORN presented, in behalf of a candidate, a specimen of *mitral stenosis and insufficiency*.

DR. JAMES E. NEWCOME presented a specimen which illustrated

CARCINOMA OF THE LIVER—OCCLUSION OF THE BILE-DUCT—ULCERATION OF THE GALL-BLADDER—BILIARY CALCULI.

The patient, a German, aged fifty-eight, bartender, came under observation December 26, 1885. He was in a state of great mental stupor, and no satisfactory history could be obtained. He had been complaining for four weeks; denied specific disease, but admitted great excess in alcohol.

On admission there was marked anasarca of subcutaneous tissue of legs, arms, and abdomen; abdomen excessively distended with fluid. No pleuritic effusion was made out. The liver was enlarged, reaching from just below the nipple to a point two inches below the right free border of the ribs. Heart normal. Urine, 1.020, amber colored, acid, no albumen or casts.

December 28th.—Paracentesis abdominis; 200 ounces fluid withdrawn, sp. gr. 1.010, eighty per cent. albumen, cloudy, light yellow, neutral, no sugar, peptones.

The patient was put upon diuretics, but the fluid rapidly reaccumulated, and he became very weak. The fluid oozed away from the puncture-wound, and this was allowed to continue under antiseptic pads. Five days after the evacuations became involuntary, the temperature ranged from 99° to 100.5° F., and on the eighth day the patient died.

Autopsy.—Heart: Some pericardial adhesion over upper surface; slight thickening of mitral valve with a few granulations of small, pin-head size. Lungs: Congestion and œdema of both lower lobes; three or four ounces of bloody fluid in pleural cavities. Kidneys: Some swelling of epithelium; otherwise normal. Spleen: Weighed five drachms; mottled capsule, interstitial and perisplenitis. Stomach: Mucous membrane atrophied and mottled; chronic gastritis. Liver: Gall-ducts occluded; numerous large whitish and reddish hard nodules throughout liver, some projecting from its anterior surface, cystic duct at upper end stopped by a gall-stone the size of a hazel-nut. The wall of the gall-bladder is one-fourth of an inch thick; its upper two-thirds shows roughening ulceration on the inner surface. Three hundred and ninety gall-stones (mostly small), facetted, found in the mucus and pus in the gall-bladder, which was not distended.

This case is of some interest as presenting two lesions, viz., carcinoma and gall-stones, either of which may stand in a causative relation to the other. Any cause obstructing the biliary flow through the liver will naturally cause thickening of the secretion, and we know that inspissated bile is the nucleus of many biliary calculi, hence carcinoma might lead to their formation.

On the other hand, where we have calculi in the gall-bladder we may have an inflammatory action set up, whereby we have exudation and thickening of the peritoneum covering the bladder, which is bound down by strong adhesions. The neighboring liver-tissue may become sclerosed and such inflammatory exudations may become the seat of malignant growths. Hence the presence of gall-stones may cause carcinoma.

In these latter cases we generally have a history of antecedent severe attacks of hepatic colic. In this particular case, the absence of any definite history renders this point purely a speculative one.

DR. WESLEY M. CARPENTER remarked that the specimen presented by Dr. Newcomb was especially interesting as one of primary carcinoma of the liver, which is very rare.

DR. J. C. PETERS said that the combination of gall-stones and carcinoma of the liver was on record in the Society's proceedings, and also a few cases of primary cancer of the liver, although almost all such specimens were secondary. One noteworthy case was that of cancer of the head of the pancreas with cancer of the liver and with gall-stones, which could be felt in the gall-bladder, almost counted, on account of the extreme emaciation of the patient. The head of the pancreas had pressed upon the duodenum, and had almost completely occluded the pyloric opening of the stomach, which became so distended that, at times, there was fluctuation in it almost like that obtained in ascites.

THE PRESIDENT recalled one case of primary cancer of the liver, and it was regarded as a rather anomalous specimen. In that case, also, the patient was tapped and the leakage plan carried out by making openings in the skin along the line of the *linea alba*, but without antiseptic dressings, as it was several years ago.

DR. NEWCOME said that the antiseptic dressing in his case consisted simply in the use of a towel wet with an ordinary antiseptic solution, and the oozing stopped within a very few hours.

DR. JOHN C. PETERS then read a

MEMORIAL SKETCH OF ALFRED C. POST, M.D., LL.D.

(see p. 274), to be accompanied by resolutions prepared by the committee appointed, consisting of Drs. J. C. Peters, R. W. Amidon, and Wesley M. Carpenter, and to become part of the published proceedings.

DR. FRANK FERGUSON presented two sets of specimens as follows:

CARCINOMA OF THE RECTUM AND LIVER.

These were removed from the body of a man fifty-four years of age, a widower, and a native of the United States. He was admitted into the service of Dr. G. L. Peabody, in New York Hospital, on December 1, 1885. His father died of cancer of the rectum. In March previous to his admission he complained of "internal piles," which frequently bled. He had considerable pain in the lower part of the large bowel and in the lower part of his spine. During this time he suffered from diarrhœa and had no formed movements. He had swelling in each groin, swollen and painful left testicle since March, 1885. His appetite all this time has been poor, and he has been frequently nauseated. He gives a well-marked alcoholic history, but has had no hard drinks for two months prior to his admission.

On admission he was poorly nourished and senile. His pulse was 88; respiration, 24, and temperature, 99°. Urine was of light yellow color, alkaline in reaction, 1.010 specific gravity, contained no albumen, no sugar, and, microscopically, was negative. During the first three weeks in December he suffered considerably from diarrhœa, having some days as many as ten movements. He had moderate distention of his abdomen, and vomited occasionally.

The last week in December his vomiting became more frequent, some days vomiting three to four times. On December 28th he was etherized, and a rectal examination revealed a mass apparently as large as a hen's egg in the anterior wall of the rectum, a little to the right of the median line. Just below this mass was felt a smaller one, as large as an acorn. Both these tumors were very firm in consistency.

The first week in January his symptoms continued, his pain being less severe.

On January 9th in some way he was told, and believed, he had a carcinoma, and he became very despondent.

During the latter part of January and first of February he was troubled with vomiting occasionally, his pain was kept under control by opiates, his abdominal distention was increasing, and he was gradually failing.

The tympanites rapidly increased after the first week in February; he was troubled with vomiting as often as four times daily some days. Pain and vomiting continued, his tympanites was very marked, and he required large quantities of morphine, frequently repeated, to keep him quiet. He gradually grew worse and on February 15, 1886, he died.

CARCINOMA OF THE STOMACH, LIVER, AND PERITONEUM.

The specimens were taken from the body of a woman thirty-five years of age, a native of Germany, and married. She was admitted into the service of Doctor G. L. Peabody, in the New York Hospital, on February 20, 1886. She gave no family history bearing on her case. She had had two children. She considered herself well until five weeks previous to her admission, which was one week after the birth of her last child. At that time her appetite became poor, she had pain in her stomach, which was relieved by the administration of opium only. Since the development of these symptoms she occasionally vomited. It was not until February 10th that she felt obliged to keep her bed. At this date she had chilly feelings, followed by fever and sweating. During this time her abdomen rapidly increased in size, she suffered from dyspnœa, and had a diarrhœa, having from two to seven movements a day. These movements were preceded by pain, from which she was free after the act of defecation. All her symptoms gradually became graver until the date of her admission, when she was troubled greatly with dyspnœa. Her appetite was very poor, she was very weak and could not sleep.

On admission her temperature was 96.2° F.; pulse, 102, and respiration 30 per minute. She was fairly nourished, anæmic, and there was slight œdema of the lower extremities. The hepatic area extended from the fifth rib above to the umbilicus. Over this area below the free costal edge on the right and in the epigastric region the surface of the liver was rough and the examination caused great pain. In the left mammary line, just below the free border of the ribs, there was an area the size of the palm of the hand in which by auscultation friction fremitus, synchronous with respiration, was obtained. The superficial glands were not enlarged. The veins over the abdomen were prominent and tortuous. There was a slight general anasarca. The abdomen was distended, tense, and fluctuating. She was cachectic and her expression was anxious.

During her short residence in the hospital she suffered considerable pain and dyspnœa. Her heart rapidly failed and she died on the 21st inst. at 6.30 A.M.

DR. CARPENTER asked Dr. Ferguson why the case was not one of primary carcinoma of the omentum.

DR. FERGUSON replied that in such a case, where the carcinoma invaded the mucous membrane, he regarded that as the primary lesion. Besides, there was evidently a continuity of the growth, which involved the mucous membrane of the pyloric extremity of the stomach, through to, and involving, the peritoneal coat, forming ing a nodular mass upon the outside, and thence extend to the neighboring organs. Furthermore, he had seen only one case of primary carcinoma of the liver, and had never seen one of primary carcinoma of the omentum, which, although it had occurred, was exceedingly rare. Wilkes and Moxon had recorded only four cases of primary carcinoma of the liver.

DR. AMIDON asked Dr. Ferguson if his rule would apply to sarcomatous growths in the abdomen.

DR. FERGUSON said that it would not; and that sarcomatous growths could begin in connective tissue anywhere.

DR. CARPENTER reported the result of a private autopsy made several years ago, in which cancer of the omentum was found, and the cancerous mass, weighing probably two pounds, had pressed against the under surface of the left lobe of the liver, where there was also superficial cancerous infiltration. It was regarded as a case of primary carcinoma of the omentum, and the lesion of the liver was believed to be secondary because the organ had been invaded only in the region where it came in contact with the cancerous mass. Undoubtedly the cancer of the stomach was the primary lesion in Dr. Ferguson's case, and he asked the question simply to further develop the pathological relations existing in the specimens.

The Society then went into executive session.

Correspondence.

VAGINAL INJECTION—AN EASY METHOD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Every gynecologist must agree with your observation, in a recent issue of THE MEDICAL RECORD, on "The Question of Vaginal Injections," that women will not faithfully carry out any treatment which involves much trouble or discomfort, either in preparation or in application. To obviate these, and secure at once the comfort and convenience of the bidet, and the advantages of the supine posture, I have been accustomed to have a broad barrel-stave, with its ends sawn off, laid across a foot-bath (or water-bucket, or other receptacle for the waste fluid) as a seat for the patient. This may be cushioned by two folded towels, so as to leave the concave centre of the stave free to conduct the fluid into the foot-bath. By placing this—raised on a box if necessary—at the end of a couch or beside the bed, the patient can lie back, while the feet rest on the floor, and the clothing, which hangs outside the seat, is wholly undisturbed.

To save fatigue some form of irrigating apparatus is indispensable; and, of all those I know, the "Reymond Siphon Syringe" is the best. Indeed, for simplicity and convenience it leaves nothing to ask, enabling the patient to take, absolutely without effort, an injection as copious or long-continued as may be desired. It consists of a rubber tube some eight feet long, which, near its upper end, is passed through two holes made in a common spring-clothes-pin that clasps the edge of the pail or other container of the injection-liquid. This end is weighted, as usual, to hold it at the bottom of the pail. The lower end terminates in a hard-rubber nozzle, a foot or so above which is placed the clamp to close the tube, and just above this a valveless bulb. The container being secured at the proper height, and the patient in position, a single squeeze of the bulb forces the air up through the liquid, which at once fills its place. Then, on opening the clamp, the flow starts and continues until the supply is exhausted.

JOHN WINSLOW, M.D.

ITHACA, N. Y., March 16, 1886.

PRACTICES OF THE COLORED TRICK DOCTOR IN SOUTH CAROLINA—AIKEN, S. C., AS A HEALTHFUL RESORT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An old negro man having general paralysis was under the care of Dr. Croft, but the wife of the patient having learned of the wonderful powers of a colored doctor then in the neighborhood sought his advice. He offered to "raise the old man up" for so much in hand and so much when he was "raised." After establishing himself at the family fireside and studying the case, he decided the patient was "tricked," and suffering from the presence of snails and worms within his body. After prayers he produced a cow's horn, with the tip sawn off,

and after lancing the man's arm placed the large end of the horn over the part lanced, and desired the wife to suck on the end of the horn and thus draw out the aforesaid creatures; the same procedure was done on the man's back. On removal of the horn it was found partly filled with worms, leeches, and a frog. A wonderful influence was effected upon all members of the family except the old man, who was not "raised up." The doctor remained at the family fireside for two or three weeks, they all being under his spell. As success had not followed they desired to get rid of him, but he would not depart, claiming the man had been "tricked" again, and that before he tried again he must marry the daughter; and if this was not accomplished at a certain time, the old man would die, and a spell fall on them—they would have fits, and on recovering would run and drown themselves.

The family became demoralized, but finally sought the doctor formerly in charge. The wife came into his office very much bewildered, saying she was under a "spell," and sought advice; she was in a state of abject fear, and trembled as she talked, as the time to marry her daughter to the "trick doctor" was at hand. After trying to quiet her fears the doctor asked if the man had a license to practise medicine; she thought he must have. After much persuasion she was induced to make a complaint to the magistrate, but doubted his power.

The "trick doctor" unwittingly wandered into town and was arrested. All through the trial he kept his eyes on the woman, and on retiring, after his conviction as a vagrant, said his spell would still work. His surgical instruments, cow's horn, and the result of the cupping in bottles, some morphia, and a license to preach are in possession of Dr. Croft. It is a good thing for the naturally superstitious colored race that the medical registration act is in force to prevent them being so actively treated as heretofore by the itinerant colored "trick doctor."

A few words about Aiken, S. C., as a healthful resort during the inclement season at the North. The presence here from year to year of those whose means enable them to seek any clime for pleasure and comfort, irrespective of bodily ills, speaks well for it. Officers of our navy, who have floated on every sea and touched all ports, winter here when able to do so.

Here and there you see cases that might better stay at home. Come early and stay late is the advice of those benefited.

Till the benefit of climate, under proper medical advice, has been superseded by a specific against the bacillus tuberculosis, it is best to take advantage of it early and continuously. Very respectfully, W. S. L.

Aiken, S. C., February, 1886.

The Fattening Effect of Chewing Gum.—A Southern paper *Macon* (Ga.) *Messenger* says: "Twenty years ago the rule was that Southern women were thin and delicate; it is not the rule now. Southern women are not physically equalled in all North America. Any physician who is as well informed as he ought to be will tell you that this is true This change is due to the habit of chewing gum. You may smile, you may even laugh, if you please, but I am telling you a plain fact. As to Southern men, they are as thin and gaunt as they ever were, and so they will remain until they cease to chew tobacco and begin to chew gum."

Meningitis following Enucleation of the Eyeball.—At a recent meeting of the London Ophthalmological Society, a paper was read by Mr. Nettleship, Ophthalmic Surgeon to St. Thomas' Hospital, in which the details were given of a case in which meningitis occurred after excision of the eyeball. The case was fatal. Only twenty-nine cases have previously been recorded, and of these twenty-five have proved fatal, making, with Mr. Nettleship's, a total fatality of twenty-six out of thirty cases.

A Man of Many Talents.—One of the most versatile of medical men of the present day is Sir Henry Thompson. He attained eminence many years ago in his own profession, specially distinguishing himself in the field of urethral surgery. He is also well known as an artist, having frequently been an exhibitor at the Royal Academy. He is not unknown as a writer and speaker, having on several occasions championed the cause of temperance reform. He is now busy with a new novel, and bids fair to attain equal renown in the field of romance.

Insomnia in the Aged and its Treatment.—In opening a discussion on this subject, Dr. C. L. Dana said that he had found the information contained in the text-books upon insomnia in the aged was very slight in amount. Insomnia was not frequent in the aged, but when it was present it was sometimes very intractable. Pathologists thought it was due to anæmia and malnutrition. The thickened arterial walls and the high arterial tension from the contracted kidneys, and similar states, which were found in the aged, would indicate that the blood-supply to the brain was deficient. The insomnia produced by anæmia was characterized by drowsiness during the daytime, the patient falling into little naps, while at night he was unable to obtain any rest. This was true of the young as well as the old. If in any case we found no actual disease, it was customary to try iron and rich diet. In the speaker's experience, however, iron did not relieve the anæmia of the aged so as to produce sleep. Alcohol with the food was another remedy, and many recommended hot gruel or hot milk with alcohol before going to bed. While alcohol would relieve some cases, there were others in which the insomnia was increased. The bromides and chloral, even when given in enormous doses, often failed to give relief. Opium was another remedy. Dr. H. C. Wood had recommended that we make our aged people opium-eaters and alcohol-drinkers. The speaker had not found that opium always agreed with the aged, and in his experience, where opium had produced sleep, it was sometimes followed by such physical and mental depression as precluded its further use. Good results had been obtained with a combination of cannabis indica and codeia; from five to six minims of the fluid extract of cannabis indica with one-sixth to one-eighth of a grain of codeia might be used. Fraser's "Trituration Tablets" were a convenient vehicle for their administration. One-fourth of a grain of the extract of cannabis indica taken alone was sometimes effective. As a rule, however, the combination with codeia was preferable. Hyoscyamine was sometimes useful, but in nervous, flighty persons it would sometimes produce an actual delirium. Under ordinary circumstances the dose should not be increased above one-fortieth of a grain to obtain the desired effect. The effect of these remedies, he thought, had been increased by the addition of from two to three drops of

tincture of aconite two or three times a day to relieve the tension of the blood-vessels. Tincture of valerian and compound spirits of lavender sometimes acted like a charm in relieving insomnia. Large doses (℈j.) of lupulin were also often effective. To recapitulate, then: In the treatment of insomnia in the aged he had been disappointed in bromide and chloral, and considered the results of opium sometimes disastrous. He recommended, therefore, good food, warm drinks at night, and small doses of codeia with canabis indica. Valerian and lavender, hyoscyamine, and lupulin sometimes were also useful drugs.—*Bulletin of Clinical Society, N. Y. P. G. M. S.*

Iodide of Sodium and Calomel in Conjunctivitis.—For inflammation of the conjunctiva, A. Bellyarminov, writing in the Russian *Ophthalmic Review*, advises the employment of iodide of sodium in large doses internally, and local treatment at the same time by blowing calomel into the conjunctival sac. This produces, after the second application, a swelling of the eyelids and of the conjunctivæ. Sometimes, also, streaks of yellowish scales may be seen on the conjunctivæ, but they fall off in three days, and by that time all the inflammation is found to have disappeared.

Yerba Santa as a Vehicle for Quinine.—Mr. J. D. Aug. Hartz, of College Point, L. I., writes: "A vehicle for the successful masking of the bitterness of sulphate of quinia has long been a desideratum to practitioners. This want has been partially met by various secret elixirs, fluid extracts, etc., which more or less accomplish their purpose, but which are mainly designed to enrich the compounders. Yerba santa, glycyrrhiza, and coffee have in turn been employed, the former with the best results. A Western firm discloses this ingredient in the name of a preparation offered for disguising quinine; other firms hide this drug under fictitious names. With a view of producing a compound which by its non-secrecy may obtain the approval of physicians who desire to prescribe intelligently, and in order to avoid the vexation to pharmaceutists by being compelled to keep on their shelves a number of preparations all designed for the same purpose, I have, after repeated experiments, compounded a mixture for which, for the sake of uniformity in designation, the name of 'Syrupus Corrigens' is proposed. One fluidrachm will so obliterate the taste of two grains of quinine that only a slight bitterness is perceptible some time after the medicine has been taken. The ingredients in a fluidounce are. Aqueous fluid extract yerba santa, f℥j.; syrup, f℥ vij.; oil of orange, ♏ jss.; chloroform, ♏ ¾."

Permanent Drainage in Ascites.—Dr. Marcell Hartwig, of Buffalo, proposes to secure permanent drainage of ascitic fluid into the subcutaneous tissues of the abdomen by means of a bent tube of gold, silver, hard rubber, or bone. The tube is to be inserted with one extremity opening into the peritoneal cavity and the other buried in the subcutaneous tissues, and left in position as long as may be necessary. Dr. Hartwig says that experience with wire sutures shows that the drain would probably remain patulous, without causing irritation, for a considerable time, perhaps years; and when ulceration did occur, it would be a simple matter to remove the tube.

The Treatment of Infantile Paralysis.—In a lecture recently delivered by Dr. William Murrell, a plan of treatment has been formulated which, it is to be hoped, may prove as successful in other hands as it appears to have been in his own. The treatment consists essentially in the administration of aconite during the acute stage while fever is present, followed, after a lapse of three or four days, by physostigma, combined still later with suitable doses of phosphorus. So much for the medicinal part; but, simultaneously with the latter portion of the treatment, recourse must be had to massage, not the massage ordinarily in use, which frequently proves inefficacious, but a massage conducted on the scientific plan laid down by Metzger, of Amsterdam, and Von Mosengeil, of Bonn. This process is divided into four forms, or gradations, first, *effleurage* (surface rubbing); secondly, friction, a more vigorous application of the preceding; then the *pêtrissage* (kneading); and, finally, *tapotement*, which is a form of percussion. When the cases are taken in hand early, a marked improvement is promptly perceived, the temperature of the affected limb approaches the normal, and the nutrition of the tissues acquires a fresh stimulus.

The Hygiene of Pregnancy.—Let the patient eat but little in the latter months, though she may eat a little frequently during the day. A large meal causes much inconvenience, due to the already enlarged abdomen. A bandage properly applied around the abdomen is useful and comfortable. She should sleep eight hours; and take an occasional bath in tepid water. If leucorrhœa be present, let her use an injection of salt water, and bathe the external genitalia with tepid water. For the breasts, use oily matters, and no alcohol. In the morning the nipples may be painted with equal parts of tincture of arnica and water, but in the evening should be covered with cocoa-butter. High-heeled shoes should be dispensed with during pregnancy.—Professor Parvin in *Coll. and Clin. Record.*

Hydrobromate of Hyoscine.—Dr. P. M. Wise, of Willard Asylum for the Insane, Willard, Seneca Lake, N. Y., writes: "The recent use of hydrobromate of hyoscine as a hypnotic, in substitution for the coarser alkaloid hyoscyamine, has led to such different experiences, as recorded in several articles in recent medical literature,[1] as to lead one to suppose the drug used by the several writers was not of a uniform nature. Hyoscine obtained for use at the Willard Asylum, where its action has been carefully observed for a number of months, was obtained through Merck's authorized agents in New York, and was delivered in original packages. To be assured that there was no 'reasonable ground for doubt that the substance employed emanated from Merck's laboratory,' it was obtained from several different importing agents in packages of various sizes, with the original seals unbroken. This is the purported source of the preparation used by the above-mentioned writers. The preparation of the aqueous solution was made with great care, and to eliminate any element of doubt with regard to deterioration of the solution, it was kept only in ground-glass stoppered bottles. The conclusions reached by the medical staff of the asylum, in respect to its value as a hypnotic, are nearly identical with those of Drs. Peterson and Langdon, of the Hudson River State Hospital (Medical Record, September 19, 1885)—that it disposes to sleep indirectly after several hours, when given in sufficient doses to produce its marked physiological effect, such as muscular relaxation, and, occasionally, stupor; but that it cannot be regarded as a hypnotic in its proper sense. Its use in active mania and melancholia was not attended with desirable results. In cases of insomnia it failed in doses short of producing its disagreeable effects—midriasis and dryness of the throat and mouth. In our experience it does not possess the value of hyoscyamine in any of the uses to which it is ordinarily applied. It has been used in doses varying from $\frac{1}{200}$ to $\frac{1}{150}$ of a grain. I may state, incidentally, that I have used it in the case of my own child, nine years of age, suffering from whooping-cough, in doses increased from $\frac{1}{300}$ to $\frac{1}{100}$ of a grain, with the effect of producing dilatation of the pupil and dryness of the throat, but without appreciable relief from the paroxysms or insomnia."

Original Lectures.

ON CERTAIN PROBLEMS IN THE PHYSIOLOGY OF THE BLOOD-CORPUSCLES.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE ASSOCIATION OF THE ALUMNI OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, MARCH 23, 1886.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF [illegible]

LECTURE I.

THE BLOOD-PLAQUE.

INTRODUCTION.—Around the blood-corpuscles still centre some of the most interesting questions in physiology and pathology, and though amid microbes and cultures we may have forgotten them for the moment, they are nevertheless still calling for solution, and perplexing this quite as much as any one of the six or seven generations which have passed away since Loeuwenhoek first detected the red corpuscles in the human blood.

The origin and life history of the corpuscles of the blood have been, and still are, among the *great secrets* of physiology. Strange, indeed, is it to think of the thousands of able observers who have gazed long and ardently, with rude and with perfect instruments, vainly endeavoring to solve the riddle constantly propounded by these common objects of study. In no department of physiology has so much labor been spent with so little apparent result. While in other lines we have penetrated to the centre of certain biological mysteries, the progress here seems painfully slow, and the discovery by Wharton Jones, in 1843, of the amœboid power of the colorless corpuscles, the rediscovery by Cohnheim of their migratory power, and the discovery of the blood-forming function of the marrow, may be said to be the most important additions to our knowledge in this generation.

The activity of research during the past decade has had, however, a perceptible influence, and there are signs of breaking in the heavy clouds which overhang the origin of the corpuscles, and the darkness is certainly less dense than it was.

A peculiarity of these perennial problems is that certain phases for the time engage the attention of observers, and the laboratory activity the world over seems centred upon them, with the result, in a few years, of an enormous increase in the literature; and after the question has been thoroughly fought out and quiet is resumed, we are thankful if only an outpost has been gained in the struggle, and we are a step nearer to the citadel of truth.

As regards the blood-corpuscles, the work of the past few years has been largely in two directions—toward the determination of the existence or non-existence of a third corpuscle in the blood, and in the study of the histological processes attending degeneration and regeneration of the corpuscles in disease; and upon these subjects I shall hope to engage your attention during this course.

I propose, therefore, in the first lecture to consider the much debated third corpuscle, or hæmatoblast of Hayem, which, so far as I know, has not yet received systematic consideration before any American or English audience. In the second I shall discuss certain histological problems connected with the degeneration and regeneration in the blood-corpuscles; and in the third I shall present a statement of recent views on the relation of the corpuscles to coagulation.

THE THIRD CORPUSCLE, OR BLOOD-PLAQUE.—*Definition.*—A colorless protoplasmic disk, constant in mammalian blood, measuringfrom 1.5 to 3.5 micromillimetres. The number per cubic millimetre in the blood of a healthy adult is about two hundred and fifty thousand, but their number varies greatly at different periods of life, and with varying conditions of health and disease. The ratio to the red is about one to eighteen or twenty. They are delicate elements, and, like the red corpuscles, tend on the withdrawal of the blood to adhere to one another, when they form the irregular granular clumps which have long been known as Schultze's granule-masses.

Name.—It will be necessary, at the outset, to refer to the names which observers have given to this corpuscle. Unfortunately they are rather numerous, and no one of them entirely satisfactory. Donne,[1] whose description is the earliest, called them *globulins*. Zimmerman[2] spoke of them as *elementary corpuscles*. Later, the collected groups were referred to as "*granular débris*," or Schultze's[3] *granule-masses*. Among the more recent observers, Hayem[4] gave the name of *hæmatoblast*, and Bizzozero[5] that of *blutplattchen—blood-plate*. Various writers refer to this element as the *third corpuscle*, while in the research of Kemp,[6] just issued from the Biological Laboratory of Johns Hopkins University, the term *plaque* is used, and has received the sanction of Professor Martin. To the terms *third corpuscle* and *hæmatoblast* there is the serious objection that these names have been applied to other bodies which have nothing to do with the elements in question. The former, to the so-called invisible corpuscle[7] of Norris,[8] and the latter to the nucleated red corpuscle of the bone-marrow. The name hæmatoblast, moreover, carries with it certain theoretical conceptions regarding the functions of these bodies which may or may not be true. I am inclined to favor the name which Bizzozero has adopted, partly because we are indebted to the distinguished Turin professor for a series of able researches which have awakened the liveliest interest in these corpuscles, and partly because usage of late has confirmed the name. Blood-plate, the English equivalent of the word *blutplattchen*, is by no means euphonious, while the French *plaque*, adopted by Kemp, is perhaps more convenient, and might be employed in the future by American and English writers.[9]

Methods of Study.—Let us first consider the plaques in blood examined in the usual manner, without the addition of any reagent; and let us suppose the blood to be taken from a case of consumption or cancer, or from

[4] Hayem: [illegible]

[5] Bizzozero: Virchow's Archiv, Bd. xc.

[6] Kemp: Studies from the [illegible]

[7] Shortly after the publication of Bizzozero's paper, Norris claimed that the corpuscles described as [illegible] "fugitive group," but a study of the beautiful photographs in his book will, I think, convince anyone with a practical knowledge of the blood-plates of Bizzozero that they are separate elements. The granules which he figures (Fig. 45) as resulting from the breaking up of the younger or fugitive corpuscles are in reality the disintegrated blood-plates. Moreover, the corpuscles which he figures are uniformly larger than the blood plates.

[8] Norris: Physiology and Pathology of the Blood, 1882.

[9] I did think of suggesting the word *disklet* as very suitable for these *little disks*, but I had not the courage to add another to the already long list; moreover, as my own name has been used in connection with these bodies, I felt absolved from further sponsorial duties on their behalf.

a new-born animal, as in these states these corpuscles are abundant. We then find, in addition to the red and colorless corpuscles, many grayish-white granular masses of various sizes and shapes. Examined at once, and if too much pressure is not exercised by the top-cover, the edges of these masses are clearly defined, and they form compact aggregations. With a power of five hundred diameters the composite structure is well seen, and the granular character is plainly discernible to be due to the

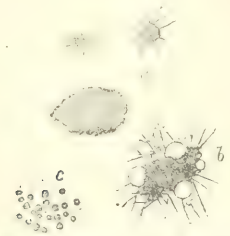

Fig. 1.—*a*, Aggregations of plaques in human blood, forming the so-called granulations of Max Schultze; *b*, disintegration of the plaques, and fibrin filaments and mucin-like spheres adhering to the mass; *c*, isolated plaques.

agglutination of numerous small bodies of uniform size. At the edges, isolated or partially free corpuscles can usually be noticed. The fibrin filaments, as coagulation proceeds, seem to radiate from the masses as centres. This remarkable conglutination of the plaques, and a tendency to undergo rapid change, have retarded greatly the recognition of the corpuscles as veritable elements of the blood. Observers have, as a rule, seen in them nothing more than a granular débris of no special significance. Nor is this to be wondered at, as they so quickly undergo changes that the clusters, in the course of a short time, really present the appearance of disintegrating protoplasm (Fig. 1, *b*). The size and shape of the groups are most variable; the more abundant, as a rule, the plaques, the larger and more numerous the aggregations; the smaller ones, composed of two or three plaques, may not equal in size a red corpuscle, while the larger ones may be ten or fifteen times the size. A tendency to adhere to foreign particles is very noticeable, and they will collect in numbers upon a fine thread of cotton or linen. In the normal blood of the adult the plaques are not very numerous, and so do not form very large collections. In some individuals, however, in health the groups are always of considerable size.

There are conditions of the blood in which, from some cause, the attraction of the plaques to each other appears diminished, and instead of forming large masses they adhere to the slide either isolated or in scattered groups of from two to ten in number (Fig. 1, *c*). Possibly this may be an accident of preparation, but I am inclined to think it not, from the fact that I have noted it in cases of malignant fever, small-pox, scarlet fever—the very states in which the normal process of nummulation of the red corpuscles may be so altered that the cells aggregate into compact clumps. In fact, the red corpuscle and the plaque in normal blood have each their peculiar mode of aggregation, the red in series and the plaque in masses. I have never seen any appearance which would suggest that the plaques have the slightest tendency to adhere by their flat surface, and to form rouleaux, as the red. It will be found too, I think, that just as there are, apart from modes of preparation, peculiarities which interfere with the normal nummulation of the red, so there are conditions in which the plaques present variations in their usual method of aggregation.

It was a consideration of the relative size of the masses, and the impossibility of their passing through the capillaries, which led me in 1873, in University College Laboratory, London, to the discovery of their corpuscular nature; and it was found that while in the blood of the young rat, when withdrawn, the masses were numerous and large, in the blood-vessels the collections, as such, never occurred, but innumerable small corpuscles, similar in character to those seen at times so plainly at the edge of the masses.

To study the plaques properly, the blood must be allowed to pass directly into a solution which, while preventing conglutination, does not materially alter their form or characters. Or they may be, perhaps, more satisfactorily observed while still within the blood-vessels.

Various solutions have been employed by different observers. Zimmerman, whose study of these corpuscles was really very complete, allowed the blood to flow directly into a solution of a neutral salt which prevented coagulation, and then in the supernatant fluid he found small colorless cells in extraordinary numbers. I have repeatedly confirmed this observation in the case of horses' blood, when demonstrating the common experiment of preventing clotting by letting the blood flow into sodium sulphate. The plaques abound in the clear serum, and if the solution is not too concentrated they are very little altered. In using the hæmacytometer (Gowers), the sulphate of soda with which the blood is mixed acts in the same way, although in the counter it is more common to find the plaques aggregated than isolated, but the individual plaques are unusually distinct. More suitable solutions for histological purposes are osmic acid one per cent., the fluids of Pacini, modified by Hayem, and of Bizzozero. Pacini's solution, as used by Hayem, consists of sodium chloride 1 part, sodium sulphate 5 parts, corrosive sublimate 0.5 part, in 200 of distilled water. Bizzozero employs the ordinary salt solution, ¾ per cent., to which methyl-violet has been added. Afanassiew recommends strongly the use of salt solution to which 0.5 per cent. of dried pepsin has been added, and 1 to 1,000 of methyl-violet, and a small amount of sublimate or carbolic acid to prevent decomposition. I find that the Pacini fluid and osmic acid answer every purpose, and in them the plaques undergo very little change.

The examination is made in the following way: Upon the thoroughly cleansed finger-pad a single drop of the solution is placed, and with a sharp needle, or pricker, the skin is pierced through the drop, so that the blood passes at once into the fluid, which is then received upon a slide and covered. The withdrawal of the corpuscles into the solution prevents the plaques from aggregating, and they remain as isolated and distinct elements. The amount of blood allowed to flow into the drop must not be large, and should be quickly mixed. In many respects the most suitable medium is osmic acid, one-half to one per cent., which has the advantage that by its use permanent preparations can be obtained. The various cells are at once fixed, and the plaques are, by this method, very well preserved. Good preparations may also be obtained by spreading rapidly a thin film of blood on a top-cover, and then placing it at once in the osmic acid. Still another method is to dry the blood in the thinnest possible layer, and then fix with osmic acid or stain with methyl-violet, and mount in balsam. Kemp recommends placing the blood-drop on a top-cover, rapidly moving it about, and then washing off the superfluous blood with salt solution. The plaques adhere to the cover, while the red cells are swept away. The cover is then quickly put in osmic acid.

For the study of the plaques in the circulating blood, the mesentery or omentum plate must be employed, and similar measures adopted to those used in the study of the circulation of the blood in mammals. The half-grown rabbit, white rat, or guinea-pig will be found best adapted for this purpose. The chief difficulties arise from the amount of fat which, in some instances, obscures the vessels, and the rapidity of the current may render it hard to see the plaques. But when, as in the omentum, a small transparent vessel is found, in which the current is slow, then with the red and colorless corpuscles the smaller plaques are also seen (Fig. 2). In

Bizzozero's paper, and in the recent communication of Eberth, full directions are given for the study of the plaques in the circulating blood. They are modifications of the original Sanderson-Stricker method (*vide* Sanderson's "Handbook"), which answers every purpose in the case of the guinea-pig, the omentum of which is a peculiarly suitable object. In the rapidly flowing current no plaques

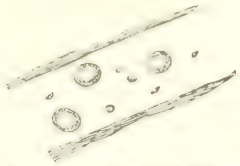

FIG. 2.—Plaques in [illegible] 1882.

are distinguishable, but when the stream is slow they can be seen here and there in the still layer with the white corpuscles, while if the current becomes very feeble, they tend to collect at the periphery with the leucocytes. In a small venule, where the stream is slow, and only a few corpuscles passing, the best opportunity is afforded of seeing the plaques. They may be well studied within the vessels in the recently killed animal, or in man, in portions of tumors, etc., recently removed. The subcutaneous tissues of the new-born rat afford perhaps the very best situation in which to study the plaques while within the vessels. The rat is killed with a snip of the scissors through the spine, and then portions of the mucoid con-

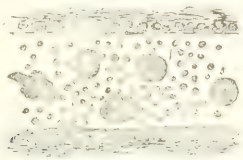

FIG. 3.—Plaques in [illegible] 1882.

nective tissue are spread thin upon the slip, either with or without saline solution. In the thin transparent vessels, the plaques are very distinct, and they remain unchanged for hours. Perhaps there is no better mode of studying these forms, as the thin walls offer no impediment to the view, and the plaques are in their natural medium. In the subcutaneous tissue of man I have had several opportunities of examining the plaques in this way, and Fig. 3 represents them in a vessel of the tissue of the scrotum an hour after its removal. In the smaller vessels of the pia mater they may also be seen.

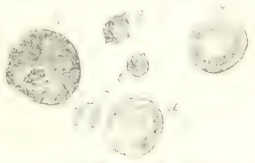

FIG. 4.—Isolated Plaques in [illegible] if nucleated.

General characters and structure.—The plaques are minute elements circulating in the plasma with the other corpuscles, and possessing such specific and distinct characters that they must be reckoned among the normal histological constituents of the blood.

The plaque is colorless, with a uniform grayish-white appearance, homogeneous or very finely granular, and presents no differentiation in the delicate protoplasm of which it is composed. So far as my observation goes, it is always colorless.

The *size* is variable. In man they may be said to measure from 1.5 to 3.5 of a micromillimetre, or from about one-sixth to one-half the size of a red blood-corpuscle. The majority of them are from 1.5 to 2.5 μ. Occasionally a plaque may be seen measuring as much as five micromillimetres, but this is exceptional. When they are abundant, remarkable gradations in size may be measured between the smallest and largest forms. They have not the constancy in size of the red corpuscle. I think in man, when very abundant, the average size is slightly less than when they are not so numerous. They are stated to bear in size some relation to the size of the red corpuscle of the animal, but we need a more elaborate series of measurements to determine this. In the white rat they are slightly smaller than in man.

The shape of the normal plaque, as seen in the vessels, is a circular disk with smooth, well-defined margin. When slightly tilted it has naturally an ovoid appearance, and when seen in profile is as a narrow, straight rod or staff. Whether they are flat disks, or biconcave, as like red corpuscles, is really not easy to determine. I should say that the majority do not show a bilateral depression, but forms are sometimes seen which resemble in outline very closely a miniature biconcave disk. Alterations in form quickly occur when the blood is withdrawn; but the natural shape, as seen in the vessel, and also, as a rule, in Pacini's fluid, or osmic acid, is as here stated.

The plaque consists of a homogeneous, smooth, structureless protoplasm of a light gray color. In the unaltered condition no nucleus can be seen, but in the fluids used to conserve them the appearance is in the form of a collection of distinct granules, which may look like a nucleus. This will sometimes, in dried preparations, stain a deeper color in the hæmatoxylon than the remainder of the plaque, and it is regarded by Hayem as a nucleus.

Changes in the plaques.—Outside the vessels the plaques are characterized by two peculiarities which have been a serious hindrance to their recognition as special elements of the blood, viz., the rapidity with which the protoplasm alters and the tendency to adhere to one another and to any substance with which they may come in contact. Within the vessels, however, they do not seem to be more prone to rapid decay than the red or white corpuscles, and in the young rat, kept at ordinary temperature, I have seen them in the vessels quite distinct and clear twenty-four hours after death. So also I have found them unaltered in the vessels of the pia mater in man, some hours after death; and, as I shall have occasion to show in the third lecture, they may in masses remain apparently unchanged for some time.

The substance composing the plaque appears homogeneous when first seen, but soon a change occurs, and

FIG. [illegible] protoplasm into a darker and clearer portion: *b*, alterations in form of plaques examined in blood-serum and watched for three hours.

the plaque presents a darker, more highly refractile portion, and a clearer substance. Usually this darker portion is peripheral, but it may be central, and then is not unlike nucleus. It is as if a material had separated from the stroma or basis of the plaque, just as the hæmoglobin of the red corpuscle may do under the influence of reagents. The plaques undergo the most curious changes in shape, to the study of which I devoted much time in 1873.' Within the vessels they are circular, but when at rest they not infrequently become ovoid or prolonged, or slightly angular. These angula-

processes may increase greatly in length, and give a stellate appearance to the plaque. The changes in form are very fully described and figured in my original paper. These alterations are probably induced by changes in the external conditions, and are not amœboid or vital in character. The addition of serum to the blood-drop, and the examination in a warm stage, afford the best means of studying the variations in form. Even within the vessels they may show these changes, and in the course of a few hours alter in a remarkable manner, so as to be scarcely recognizable.

A very common change is the separation from the plaque of a mucin-like (?) material in the form of a pale sphere, which may remain attached to the cell or separate from it. When aggregated in masses, as in a slide of fresh blood, this process can be readily seen at the margin, and the field in the vicinity may be covered with these pale globular bodies. They result, doubtless, from the separation of a material from the substance of the plaque, and are identical with the spheres so often seen attached to spermatozoa in urine.

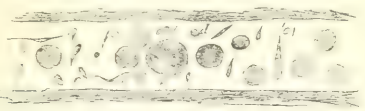

FIG. 6.—Alterations in the Plaque while within the Blood-vessels, sketched after three hours on the warm stage. April 6, 1885.

In marked contrast to the stability of the plaques within the vessels is their rapid disintegration when withdrawn. At a low temperature this does not occur so quickly, and of this Hayem took advantage in his researches; but at the ordinary temperature, and in the examination of the blood without any reagent, the plaques unite with each other and undergo rapid change—a viscous metamorphosis, as Eberth [1] terms it. As I shall have occasion to point out, this is associated with the separation of fibrin which seems to arise first about the groups of plaques, as Ranvier [2] noted in 1873, and he spoke of these little granulations—*grains sarcodique* of Vulpian—as centres of coagulation.

Action of reagents.—This has already been referred to in the consideration of the best modes of examining and preserving the plaques. Water reacts upon them as upon the colorless elements, causing a swelling of the protoplasm and a rapid production of the pale spheres already described. Dilute acid and saline solutions act in the same way. In three-fourths per cent. salt solution, or in the sodium sulphate solution for blood-counting, they retain their outlines and do not so rapidly coalesce and disintegrate. Dilute potash solution causes speedy dissolution.

The aniline dyes stain the plaques as other protoplasmic bodies, and Bizzozero's fluid has the advantage of tinting them and making them more distinct. In preparations by Ehrlich's method, the tint of the central portion of the plaques may be deeper than the periphery. Carmine appears to have no effect. For permanent preparations the dry method is the best, and they may be stained with hæmatoxylon, fuchsin, Bismarck-brown, or methyl-violet. The blood in osmic acid may be kept for some days if the cover-glass is carefully surrounded with paraffine. A solution of corrosive sublimate 1 to 1,000 is also suitable for their preservation.

The precise chemical composition of the plaques has not been determined, but from the similarity in most points of their reaction and behavior with dyes to the nuclei of cells we may suppose their composition to be of a similar nature.

The number.—The numeration of the plaques presents serious difficulties, on account of their extraordinary adhesiveness, and the numbers now given may be subject to revision when better methods are devised. In my own case the numbers range from 250,000 to 300,000 in the cubic millimetre; figures which correspond to those of Hayem. Full-blooded, plethoric individuals have rarely more than 250,000 per cubic millimetre. The variations in the same individual may be considerable during the day, and they seem increased after a full meal. Age has an important influence; in the infant and young child the number may be double that of the adult. In the new-born of all the mammals I have examined they are specially abundant. As age advances they seem again more numerous, particularly if the individual is weak and debilitated.

Until more extensive and more reliable counts are announced, we may say that the plaques in health number between 200,000 and 300,000, the ratio to the red being about 1 to 18 or 20, and to the white corpuscles 35 or 40 to 1. The numeration of the plaques is a much more tedious matter, and requires far more patience than counting the red and white corpuscles. Rapidity is essential to success. I find the *compte-globule* of Malassez rather more adapted than the Gowers apparatus, as the mixture can be more thoroughly and quickly made. The blood is got from a deep puncture and aspirated into the tube of the Potain mixer to the line, and then the Pacini's fluid or osmic acid is immediately drawn in. Frequently it will be found that, with the greatest care, the plaques have run together and the process must be repeated. It is essential, too, in the first aspiration of the blood, to reach the line at once; if the blood-column goes beyond, it must be discarded and a fresh attempt made, as the time lost in accurately adjusting the column would be sufficient to allow the plaques to coalesce.

The plaques in disease.—In health the plaques are relatively scanty, and they aggregate into such small, scattered groups that they do not necessarily excite the attention of the student, but every constant observer of the blood in states of disease must have marvelled again and again at the extraordinary number and size of the granule-masses met with in certain cases. Led away by their constancy and peculiar characters, writers have regarded them as specific and distinctive elements in some affections (leukæmia, phthisis). From the able and comprehensive paper of Riess to the more recent one of Afanassiew,[1] there have been very many observations on the frequency and significance of these bodies in disease, but we still lack careful and painstaking enumerations in the various acute and chronic diseases. A rough estimate of their increase or diminution may be made by anyone well accustomed to their observation, but for scientific accuracy the hæmocytometer must be used, and means must be devised to overcome the present serious source of error.

My own observations have been very numerous, and I have for years been in the habit of noting the paucity or abundance of these elements. In the absence, however, of systematic and reliable counts, the notes are not worth much. The general results I may state as follows:

1. The plaques are increased in all chronic wasting maladies—cachexiæ—with or without fever.

This is very evident by examining in rotation the various patients in a hospital ward. The debilitated individuals, the subjects of phthisis, cancer, or other chronic wasting diseases, present a marked increase. In phthisis the number per cubic millimetre may reach five hundred thousand or more, and the ratio of the plaques to the red may rise as high as 1 to 5.

2. In acute sthenic fevers the plaques are not increased in the early stages, but as the disease advances, and the patient becomes weaker and more debilitated, the increase is usually marked. This is well seen in typhoid fever, in which the number of plaques during the first week may not rise above normal, while in the third and fourth week there is usually a notable increase.

[2] Ranvier: Gaz. Méd. de Paris, 1873.

[1] Afanassiew: Deutsches Archiv f. klin. Medicin, Bd. [illegible].

3. In the so-called blood diseases the number of the plaques is variable. Many observers have remarked the great numbers in certain cases of leukæmia, but in others the increase is not apparent. So, also, in lymphatic anæmia. In some cases of Hodgkin's disease I have seen the plaques in extraordinary numbers. In profound anæmia the plaques may be very scanty. I have long noted, in cases of pernicious anæmia, that the clusters of plaques may be almost absent, or much more scanty than in health.

Distribution of the plaques in animals.—So far as our present knowledge goes, the plaques are constant constituents of the blood in mammals, and, with the exception of slight variations in size, the general features are the same in the various orders. My observations on this point have not been extensive, but I can speak of their presence in the blood of the dog, cat, mouse, guinea-pig, rabbit, sheep, ox, horse, pig.

They also occur in the ovipara, and here they are nucleated. Kemp states that in the blood of oviparous animals there is a nucleated corpuscle which is physiologically analogous with the plaque in the blood of mammals, and which behaves like it when the blood is drawn.

Origin.—Various explanations have been given to account for the origin of the plaques, and Kemp enumerates no less than seven different views. Perhaps the most prevalent idea, particularly among clinical physicians, is that they result from the disintegration and degeneration of the blood-corpuscles, especially the leucocytes. This is really not unnatural, for the irregular clumps of plaques in blood examined in the ordinary way look very like—and, indeed, are—protoplasmic débris, but we know of no such process of rapid disintegration in the colorless corpuscles, which are remarkably stable elements, and even in their death and decomposition never, so far as I can make out, produce structures similar to the groups of plaques. The fact that the formation of the *granular débris*, as the groups of plaques are called, can be prevented by drawing the blood directly into a drop of osmic acid (or Pacini's fluid), in which the elements are fixed instantly, should be sufficient to convince the most sceptical; but if it does not, the study of the plaques in the new-born rat will satisfy, I think, the most obdurate. The abundance and large size of the groups of plaques in a blood-drop examined in the ordinary way, the ready demonstration of the individual elements in the blood-vessels of the subcutaneous tissue, and the identity of these with the corpuscles at the edges of the groups, and with those in the osmic acid drop, render the conclusion irresistible that we are dealing with something quite independent of the colorless corpuscle.

I am unaware of a single observation corroborative of the view that the plaques result in any way from the degeneration of the red corpuscles. We need not consider the views that the plaques represent fibrin particles, or are depositions of globulin.

A majority of observers regard the plaques as independent elements in the blood, others agree with Hayem that they are young red corpuscles—hæmatoblasts—and a further discussion of this point will be best considered in the next lecture, when I speak of the regeneration of the corpuscles.

Historical.—I do not propose to enter exhaustively into the literature of the blood-plaque. This has already been done very fully by several German observers, and quite recently by Kemp, whose paper on the "Studies from the Biological Laboratory of Johns Hopkins University" will be accessible to all American and English students. In my original paper I have also given pretty fully the older references. We may conveniently divide the work which has been done in this department into three periods. The first embraces the time prior to the publication of Hayem's researches in 1877. The masses had been observed frequently, and the corpuscles had been studied, notably by Donné, Zimmerman, and Max Schultze. In 1874 I demonstrated the corpuscular nature of the granule-masses, and showed that the bodies of which they were composed "were present as separate elements in the vessels, and showed no tendency to adhere together." In 1873 Ranvier[2] called attention to their possible association with fibrin formation. Riess and others had called attention to their increase in disease. The second period dates from the publication by Hayem, in 1877–78, of his researches, and to him really belongs the credit of establishing the histological position of these corpuscles as constant blood-elements. It is curious that his careful observations met with very slight recognition among physiologists. The interest in the question had, indeed, almost died out when, in 1882, Bizzozero, of Turin, published an exhaustive article in Virchow's *Archiv* upon the *Blutplattchen*, and their relation to fibrin formation. From this we date the third period, during which there have been already published eighteen or twenty essays, chiefly in Germany, and the most intense interest seems to have been aroused on the subject. The weight of histological evidence is strongly in favor of the views which I have here laid before you, but there still remains the greatest diversity of opinion as to the function of these bodies in blood development, and of their relation to the formation of fibrin, and upon these questions I shall have more to say in the second and third lectures.

Original Articles.

THE BENEFIT TO BE DERIVED FROM SYSTEMATIC WASHING OUT OF THE STOMACH, IN CASES OF GASTRIC DILATATION DUE TO HYPERTROPHIC OR CICATRICIAL STENOSIS OF THE PYLORUS.[1]

By FRANCIS KINNICUTT, M.D.,

Although Canstatt first recommended the frequent withdrawal of the accumulated fluid in the stomach by means of the stomach-pump, in cases in which the patient had lost the power of vomiting, its systematic use in cases of marked gastrectasia was first instituted by Kussmaul, in 1879. The results obtained by him were so favorable that this method of treatment at once obtained recognition, and of late years the washing out of the stomach by means of the stomach-pump or by the siphon process, has been successfully employed in the treatment not only of gastrectasia, but also of gastric affections of various kinds.

During the past year, three cases of extreme dilatation of the stomach from pyloric obstruction, have been treated in my wards at St. Luke's Hospital. The histories of Cases I. and II. illustrate the benefit which may be derived from systematic lavage of the stomach by means of the siphon process.

Case I.—M. P——, female, aged thirty-nine. Admitted to hospital February 4, 1885.

A sister died of cancer of the breast; family history otherwise good. During a period of ten years, until the patient reached her thirtieth year, she suffered from frequent attacks (every few weeks) of violent epigastric pain, usually after meals, followed by vomiting of the contents of the stomach. The pain was only relieved by hypodermatic injections of morphine. There was never any blood in the vomited matter. During the past several years, she has been quite free from these attacks and, until a year ago, apparently enjoyed fair health. Her weight at this date was two hundred pounds. At about this time, she began to have frequent attacks of vomiting. At times, the vomiting occurred within a few minutes after the ingestion of a meal; again, an attack

[1] [illegible]
[2] [illegible]

would occur only once in two or three days, when as much as "several pints" of partially digested food was vomited. At first, there was an absence of other symptoms; gradually, however, more or less constant nausea and intense burning pain in the epigastrium supervened. The patient rapidly emaciated, losing one hundred pounds in weight within the year, lost strength, and was finally confined to her bed. There was obstinate constipation. On admission to hospital, the patient was extremely weak, anæmic, and emaciated. There was anorexia, a thickly-coated tongue, and constipation. There was also constant nausea, foul-smelling eructations, an intense burning sensation and pain in the epigastrium. The temperature was normal; the urine was free from albumen and sugar.

Physical examination revealed a marked depression just below the ensiform cartilage and beyond, marked distention of the abdomen, with distinctly-outlined borders; the lower border reached a point three inches below the umbilicus in the median line, and extended thence obliquely to the extreme limit of the left iliac region.

There was marked tympanitic resonance over nearly the whole area of the distention, and succussion on palpation. Distinct undulatory movements, passing from left to right, were visible. There was slight enlargement of the inguinal glands. Examination of the heart, lungs, liver, and spleen gave negative results.

Two days after admission, no vomiting having occurred in the interval, the patient vomited two quarts of semi-fluid matter, containing fragments of meat eaten *previous* to admission.

After complete evacuation of the contents of the stomach by vomiting and by means of the stomach-tube, a small tumor, the size of an almond, could be felt distinctly, one inch to the right of the median line and two and one-fourth inches above the umbilicus. It was of firm consistence, was easily movable within narrow limits, and readily slipped from under the finger. It was found that the stomach easily retained ninety-two ounces of fluid, introduced by means of the œsophageal tube.

A mechanical dilatation of the stomach, from pyloric obstruction of a doubtful nature, evidently existed. A systematic daily washing out of the stomach by the siphon[1], and careful feeding, were at once instituted.

The method adopted was to wash out the stomach thoroughly with a weak solution of boracic acid, early each day, before food was taken. A pint of peptonized milk was then given by the tube or mouth. A similar quantity of milk was given at varying intervals during the day, and at first lavage again was regularly employed in the afternoon. The rule was adopted, also, to evacuate the contents of the stomach by means of the tube, *whenever* marked epigastric distress followed a "feeding." The relief of the burning sensation and epigastric pain, and of the vomiting, was rapid and marked. Broths and beef-solutions were gradually added to the diet. Aside, however, from the alleviation of the above symptoms, little progress was made during the succeeding five weeks. The digestive power of the stomach evidently was seriously impaired. The daily lavage showed the presence of foul-smelling, undigested matter in the fluids withdrawn from the stomach. At the end of two months distinct improvement in this respect was observed, and the patient began to increase in weight. On February 4th, her weight was 99 pounds; on April 7th, 102 pounds; April 21st, 103 pounds. On April 24th, there was a *spontaneous* evacuation of the bowels, the first for a year. From this date, natural movements, without the use of cathartics or enemata, occurred with more or less regularity. On May 5th, the weight was 108½ pounds; May 12th, 110 pounds; May 19th, 112 pounds. On May 20th a small amount of meat was added to the diet, but given only after thorough lavage. It apparently was easily digested, and from this date it was allowed daily. On May 26th the patient's weight was 120 pounds; June 9th, 124½ pounds; June 16th, 127 pounds. On May 27th a small amount of uncooked rice was given to the patient, and three days afterward a portion of it, at least, was withdrawn from the stomach by means of the siphon. On several occasions during June, lavage was discontinued temporarily, by my directions. Epigastric distress and vomiting at once recurred, and the patient earnestly begged that the daily washing out of the stomach might be renewed. During the period of the employment of lavage, the reaction of the urine passed at successive periods, during the twenty-four hours, was tested,[1] and found to be constantly alkaline. The patient, while under observation, suffered from time to time from tetanic spasms of the calves of the legs.

Kussmaul explains both the muscular spasms and the epileptiform convulsions which not infrequently occur in cases of dilatation of the stomach on the ground that there is a deficient absorption of fluids by the stomach in this condition, through which an abnormal dryness of the muscular and nervous tissues is induced (Ziemssen's "Cyclopæd. of Med.," *loc. cit.*). Bouchard refers the symptom to an auto-infection by toxic products of fermentative and putrefactive changes in the stomach (article on "Dilatation of the Stomach," by W. H. Welch; Pepper's "System of Medicine," vol. ii., p. 596).

The marked improvement in the patient's condition during the above period of four months, and the absence of appreciable growth of the pyloric tumor, pointed to the non-malignant character of the obstruction. The patient was unable to use the stomach-tube herself, yet without its daily use a considerable prolongation of life seemed impossible. She was most anxious that operative interference, which afforded a possibility of permanent relief, should be attempted. The case seemed a suitable one for Loreta's operation of digital dilatation of the pylorus, and after a consultation of the physicians and surgeons of the hospital, it was determined upon. The result has been reported elsewhere by my colleague, Dr. McBurney.[2] The pyloric obstruction and tumor were found to be due to a purely hypertrophic process, affecting the submucous and muscular tissues of the pylorus.

Case II.—S. J——, female, aged fifty-nine, admitted to hospital April 9, 1885. The patient had previously been an inmate of the hospital for a brief period, in the winter of 1883. She at that time gave the following history: From fourteen to nineteen years of age, she suffered from occasional attacks of hæmatemesis. At the age of nineteen, after severe exertion, she vomited a large amount of blood. Again, twenty years ago, she vomited almost daily, for a year, black grumous material, in varying quantities. In the early part of 1881, she had a severe hæmatemesis. She was admitted to hospital in December, 1883, much emaciated, complaining of severe epigastric pain, and vomiting after food. The stomach was found to be greatly dilated, and there were the physical signs of slight changes at the apex of the right lung.

She was discharged after a short stay in the hospital. She has continued to vomit since this date, at least once daily, and has lived almost wholly upon a milk and fish diet. Last July, she had an hæmoptysis, and during the past winter her cough has been troublesome. She has suffered from almost constant epigastric pain, at times so severe as to require hypodermatic injections of morphine. Her bowels have been obstinately constipated for more than a year, never being moved without the use of cathartics. For the past six weeks she has been con-

[1] The tubes used [illegible] were [illegible] mann, of New York. The French tube and funnel are made in one piece. Both tubes are of soft, flexible red rubber. An irrigator was attached to one end of the tube for greater convenience in use, and a Y-shaped glass tube was connected by one arm with the tube running to the irrigator, and by the other with a discharging tube.

[1] An alkaline reaction of the urine during the treatment of gastric ectasia by lavage has been noted by many observers. It has been suggested by Quincke that this mode of treatment diminishes the absorption of the gastric acids, and thus withdraws an important factor in the acidification of the urine (Ziemssen's Cyclopæd. of Medicine, vol. vii., p. 318).

[2] New York Medical Journal, January 16, 1886.

fined to her bed. On admission, the patient was greatly emaciated, weak, and anæmic. The tongue was thickly coated; there was anorexia, great thirst, and constipation. She complained of constant distress and pain in the epigastrium, and of foul-smelling eructations. The urine was scanty; alkaline in reaction; it contained neither albumen nor sugar.

Physical examination revealed a localized distention of the abdomen, occupying the umbilical, hypogastric, and left lumbar regions. The lower border of the prominence reached a point two inches below a line drawn through the anterior superior spinous processes of the ilia. There was a resonant percussion note over the greater portion of the above area and succussion on palpation. On complete evacuation of the contents of the stomach by means of the siphon, a tumor of about the size of an almond could be distinctly felt in the epigastrium, two and one-fourth inches above the umbilicus in the median line. It was immovable and of firm consistence. There was sensitiveness over its site, on firm pressure. It was found that the stomach could easily receive and retain one hundred and fifteen ounces of fluid. Consolidation, with areas of softening, was found at the apex of the right lung. Examination of the remaining organs was negative. There was no enlargement of the superficial glands. The patient's weight was eighty-seven pounds. The dilatation of the stomach was evidently due to pyloric obstruction, and a cicatricial or hypertrophic stenosis was believed to exist. An exactly similar method of treatment to that pursued in the previous case (daily lavage and careful feeding) was instituted. On April 14th there was no vomiting, and for the first time for many months morphine was not required. The fluids withdrawn from the stomach continued to be extremely offensive for the first month after daily lavage was adopted; the eructations, the epigastric distress and pain, and the vomiting, however, were greatly relieved. The vomiting only very occasionally recurred. From May 8th, there were daily spontaneous movements of the bowels. On May 16th, a little toast was allowed for lunch. On May 19th the patient's weight was 88½ pounds; on the 20th, meat, after lavage, was ordered. It was found that it could be taken without distress. May 26th, the weight was 90 pounds; June 2d, 91 pounds; June 9th, 93 pounds; June 23d, 99 pounds. A gain of 12 pounds, in the presence of a progressing tubercular affection of the lungs, had been obtained in a period of a little less than three months. The necessity and efficacy of the method of treatment had been demonstrated; life could be prolonged, however, only by its continuous employment, and this was found to be impossible outside of the hospital. The patient earnestly begged that a surgical operation should be attempted, and after consultation with the surgeons of the hospital, Loreta's operation was determined upon. Dr. McBurney also has reported the subsequent history of this case.[1] The cause of the pyloric stenosis is one of great interest, as demonstrating a condition which must be of very unusual occurrence. The nature of the pyloric tumor is also of interest. The following report is taken from Dr. McBurney's notes of the case:

"On opening the stomach, an old and apparently healed ulcer was felt and seen, directly opposite the incision. . . This ulcer was about an inch in diameter, and its largely-thickened edge formed the tumor which had been felt before the operation. . . The base of this ulcer was firmly adherent to the pancreas behind, and the contraction of cicatrization had given the stomach an hour-glass form. . . Even then it was difficult to find the pyloric orifice. . . After a search of some minutes, I found it at the upper border of the ulcer, close to the latter, but not involved in it, and directed upward. . . The posterior edge of the pylorus had been so firmly drawn by the cicatrization of the ulcer that, although it was easy, by lifting the anterior edge, to pass the finger through it, yet when the anterior edge was not so lifted, the orifice was completely closed."

Several practical points are suggested by a study of the histories of these cases. They are, (1) that systematic daily lavage of the stomach is often capable, not only of relieving distressing symptoms, but also of, partially at least, restoring the digestive power when seriously impaired, in cases of gastric dilatation due to hypertrophic or cicatricial stenosis of the pylorus; (2) that improvement in the latter respect is frequently attainable only after weeks of persistent treatment;[1] (3) that considerable prolongation of life with the existence of a pyloric stenosis of the degree described above is improbable, in the absence, either of the continued employment of this mode of treatment, or of surgical interference.

Case III. was that of a woman, aged twenty-eight, who died in hospital previous to the admission of those whose histories have been related. Her statements in regard to her health, previous to a few months before admission, were contradictory and unsatisfactory. On admission, January, 1885, she stated that her present symptoms first appeared three months ago. At about this date, she began to be troubled with epigastric distress, occasional vomiting, and abdominal distention. For the past month, she has vomited daily. Frequently, food taken on one day has been distinguishable in the vomited matter of the next. She was greatly emaciated, weak, and distinctly cachectic. The tongue was thickly coated, there was intense thirst, anorexia and obstinate constipation. She suffered greatly from eructations, epigastric distress and pain. The temperature was normal; the urine, acid in reaction, sp. gr. 1.024; it contained neither albumen nor sugar. On examination, the outlines of the stomach were distinctly visible through the abdominal walls. The lower border reached a point considerably below the umbilicus, in the median line. There was marked succussion on palpation, and the peristaltic movements of the stomach, passing from left to right, were plainly discernible. A tumor, the size of an English walnut, was detected one inch above the umbilicus, in the median line. It was of firm consistence, and was easily movable within narrow limits.

Examination of the heart, liver, and spleen, gave negative results. There was no enlargement of the superficial glands.

The presence of a marked cachexia, the comparatively recent date of the occurrence of abdominal symptoms, the existence of a presumably pyloric tumor, warranted, it seemed to me, the diagnosis of malignant disease. Palliative treatment only, with the irregular employment of lavage, was therefore prescribed. The emaciation and weakness rapidly increased; the patient continued to suffer from epigastric distress and pain, and vomiting, and finally died, without the occurrence of other than the above symptoms, seven weeks after admission.

Examination after death showed that, with the exception of small areas of catarrhal pneumonia in the lower lobe of the right lung, and slight changes in the connective tissue of the liver, the morbid changes were confined to the stomach. The stomach was enormously dilated. The pylorus was greatly thickened, and its orifice barely admitted the tip of the little finger.

A large cicatrix, two inches in diameter and of regular outline, was found in the immediate vicinity of the pylorus.

The pyloric tumor was found, on microscopical examination, to consist of an increase in the normal elements of the muscular and submucous coats of the pylorus.

The results of the autopsy illustrate the difficulty of positively differentiating dilatation of the stomach, due to hypertrophic or cicatricial pyloric stenosis, from that resulting from malignant disease of the pylorus.

[1] New York Medical Journal, January 16, 1886.

[1] As the stomach [illegible] allowed to stand separated into the layers which have been considered to be indicative [illegible] of the digestive function.

The obstruction evidently had existed for a long period, sufficiently long to seriously impair the digestive functions of the stomach. A cachexia was produced, which in no respect was distinguishable from that accompanying malignant disease. I am inclined to believe that if the true nature of the affection had been recognized and *systematic* lavage of the stomach employed, as in the previous cases, a very considerable prolongation of life might have been attained. The case suggested to me a different method of treatment, in the presence of similar symptoms.

Cases I. and II. are examples of a pathological process, which I believe is of more common occurrence than is generally recognized.

In Case I. the most careful examination of the stomach failed to reveal the presence either of an ulcer or a cicatrix, and it properly may be considered, therefore, as one of purely hypertrophic pyloric stenosis.

In Case III. the cicatrization of an old ulcer may be regarded as a factor in the pathogenesis of the hypertrophy of the tissues of the pylorus.

Hypertrophic stenosis of the pylorus has been described by various observers, particularly by Lebert [1] and Habershon.[2] The latter considers it to be due to a fibroid degeneration of the "pyloric valve," affecting its mucous and submucous coats, usually the latter, associated with a compensatory hypertrophy of the muscular coat of the pylorus.

In conclusion, I would add a word in regard to the means which I have found most efficient in determining the size of the stomach in cases of suspected dilatation. Frerichs' method of determining its contours by artificial distention, through the generation within the stomach of carbonic acid gas (introducing bicarbonate of sodium twenty to thirty grains, and tartaric acid fifteen to twenty grains, in solution), has often failed in my hands. Auscultatory percussion of the stomach, artificially distended by the above means, has given somewhat more satisfactory results.

Leube's method of sounding, which consists in introducing a tube into the stomach, and attempting to feel it with, or catch it between, the fingers through the abdominal walls after insertion, also has proved unsatisfactory. A tube sufficiently soft to be unattended with possible risk in the necessary manipulation, permits of a coiling upon itself, which militates against a correct estimation of the degree of dilatation.

Penzoldt's modification of Piorry's method, I have found both safe and comparatively accurate in application.

It consists in withdrawing the fluids from the stomach by means of the stomach-tube, thus causing dulness to disappear; and in then making the latter reappear by injecting more fluid. "By noting the lower limit of dulness thus produced, the position of the lower border of the stomach may be determined."

I desire to express my indebtedness to the gentlemen of the medical house-staff of the hospital, Drs. Sherman, Tieman, and Densch, for their assistance in carrying out the method of treatment described.

THE CURE OF TUBERCULOSIS.—A subscription for the purpose of encouraging researches in the therapeutics of tuberculosis has been opened by the *Gazette Hebdomadaire de Médecine et de Chirurgie*, of Paris. The idea of a subscription for this purpose was suggested by M. Verneuil, and in a few days the sum of over four thousand francs was raised.

VENICE TURPENTINE IN CHRONIC POSTERIOR GONORRHŒA is highly recommended by the editor of *The American Practitioner and News*. It should be given in large doses.

AN ANALYSIS OF SEVENTY-SEVEN CASES OF TRACHEOTOMY.

BY ROBERT W. LOVETT, M.D.,

ASSISTANT SURGEON TO THE NEW YORK ORTHOPÆDIC HOSPITAL.

IN the year 1885 tracheotomy was done seventy-seven times for pseudo-membranous laryngitis, at the Boston City Hospital. Of these cases 20 recovered and 57 died; 25 died with septic symptoms, and 26 with symptoms of extension of membrane to the trachea and bronchi, 4 died of heart failure during or after operation, and 1 each of pneumonia and peritonitis. This classification of the causes of death is of course purely arbitrary; when a child died with symptoms of strangulation the case was set down as dying of extension. When septic symptoms and stupidity were predominant and the breathing was not labored the death was classed as septicæmia. The two divisions often overlapped markedly. Of the four cases of heart-failure, one, not anæsthetized, died before the trachea was opened, one was practically dead before operation, and the other two, both feeble children, died, one during and the other just after a simple and not markedly bloody operation. No one of these four children was anæsthetized. They were all between two and three years old.

The cases put down as septic died very much more quickly after operation than did the extension cases. The twenty-five septic cases lived, on the average, forty-eight hours while the twenty-six extension cases averaged eighty-one hours after operation.

The ages of the children ran from nine months to two years, but the bulk of the cases lay between two and seven years. The youngest recoveries were two children fifteen months old, who both nursed throughout their illness. The recoveries and deaths were quite equally distributed among the children of all ages.

A very bad class of cases comes to the hospital; the majority are sent in only as a last resort; some are brought in *in extremis*, and one or two died before tracheotomy could be done. When the parents desired it, and as a means of euthanasia, the operation was done even in the most hopeless cases. Twelve or more of them were of that very offensive sort that is accompanied by gray or greenish membrane in the throat and an intolerable odor, with, of course, much sepsis. With one exception these all died. The majority of the children were brought during the first or second day of their dyspnœa. In forty-four cases the operation was performed on the first day of the croup, and in sixteen on the second. In no case was the operation done later than the third day. The average time of operation was the same in the cases that died and the cases that recovered—thirty-two hours after the beginning of the croup. Croup supervened on the diphtheria from the second to the tenth day of the disease, averaging the sixth. In the cases that recovered the operation was performed on the sixth day of the disease, on the average; in both extension and septicæmia cases the average day of operation was between the fourth and fifth. That is to say, in favorable cases the croup did not come on so rapidly as in the cases that died. In the treatment no delicate distinction between croup and diphtheria was attempted; they were all classed and treated as diphtheria, and most of them presented unmistakable signs of it. In forty-eight of them diphtheritic membrane was seen in the pharynx by some of the hospital staff. In sixteen no examination was noted; in many of them none was made on account of the haste or the child's bad condition. In thirteen the child's throat was examined and no membrane was seen. Nevertheless several of these children showed marked signs of diphtheria; one gave post-mortem evidence of it in the form of a septicæmia, two had every sign of it except pharyngeal membrane, another had been exposed to it in the family, etc. Setting aside four of these thirteen who certainly had diphtheria, we have nine cases

where the diagnosis of diphtheria could not be made. Four of these nine cases recovered.

The operation done was ordinarily the high one, and anæsthesia was not used in more than one-half of the cases. Ordinarily, without it there was but little suffering, as the child was stupefied by the lack of oxygen. Sometimes the operation seemed painful throughout, and sometimes only the first cuts caused suffering. Ether invariably produced spasm and more labored breathing; chloroform was readily taken, and excited no spasm. After the use of either anæsthetic, and especially ether, there was apt to be a marked collapse after the operation. No child died in this condition, but only because they were carefully watched and strongly stimulated.

As to tracheotomy as a means of euthanasia, where septicæmia prevailed the death was easy enough and a state of stupidity preceded the end by many hours, but in every one of the twenty-six extension cases the death was preceded by gradually increasing dyspnœa, which became, in many cases, frightful to witness. The suffocation which comes before tracheotomy, seems to be of a rapid sort, which soon stupefies the child by its intensity, and makes the end a comparatively painless one; but the dyspnœa which comes after tracheotomy, as an accompaniment of the extension of membrane, is so gradual an affair that it reaches a much more acute stage before it stupefies the child. Unless septicæmic, the child is keenly alive to its suffering; cyanosis and retraction of the soft parts of the chest come on, the discharge from the tube is suppressed, and the breathing whistling. Restlessness and much suffering are only too apparent. The condition of affairs grows worse until the child dies in a paroxysm of dyspnœa, or, after hours of acute suffering, becomes comatose. Tracheotomy is not a means of euthanasia in cases that die by extension of membrane.

Albumen was present in the urine of nearly all the bad cases that were examined. The investigation of this point was very unsatisfactory, as it was very difficult to collect the urine of such small and such sick children. The urine was examined in 35 cases; 28 of these had from one-fourth to one-half per cent. of albumen. When it could be watched, it appeared toward the close of the first week of the disease, increased for a week or ten days, and in the course of a fortnight more it disappeared. It seemed to have no particular significance, and was equally distributed among all three classes of cases, except that it was constantly present in large amounts in bad septic cases.

More or less enlargement of the superficial cervical glands was noted in all but five cases; this varied from a few lumps to a neck as large around as the head. These large necks accompanied only very septic cases, and usually foul ones. A progressive enlargement of the neck was one of the worst possible prognostic signs, and, with the exception of one case, there was no recovery where the neck reached any considerable size. This one case was as septic and foul and hopeless as any in the series, and the swelling of the neck was simply enormous; but from the fifth day improvement was steady.

Nasal discharge was very common and without any especial significance. It is noted as having been present in fifty-five cases, and was equally distributed among all classes; nose-bleeding was present in six fatal cases. The character of the discharge from the tube was a most interesting indication of a case's progress. At first it was always bloody, and ordinarily loose. In twenty-four hours, the blood would disappear and the discharge would be whitish or yellowish, and thick or loose, but so long as it was free and not sticky it was favorable. The discharge was apt to become bloody at any time in any case, and it seemed to have no significance. Blood appeared as late as the fifth day in favorable cases, and in any case was apt to disappear and return again, and sometimes be present for one or two days at a time. But marked diminution in the amount of the discharge was a most ominous sign. The discharge then became sticky or gummy, and in many cases complete suppression of the discharge followed, preceding death. In only four cases that recovered, all bad ones, did the discharge at any time become gummy, and then only for a short time. In the other favorable cases, the discharge was free throughout.

In fatal cases a gummy discharge was generally present as a precursor of death; it appeared ordinarily within twenty-four to forty-eight hours of the end, sometimes coming temporarily a day or so earlier. This suppression of the discharge accompanied both septicæmia and extension cases, but in the latter dried pellets of mucus were apt to be present in the trachea, and to cause much choking and sometimes death. The condition of the trachea was seen, post-mortem, in two cases of this sort, and both showed fibrinous bronchitis and laryngitis, and fibrino-purulent bronchitis of the smaller tubes, with a mild degree of septicæmia, shown by cloudy swelling of the other organs. In a word, the drying of the discharge is one of the worst prognostic signs. The temperature, probably, possessed no more than its ordinary prognostic value in acute septic diseases. It went up to 107° in 3 fatal cases, and in 34 cases where it reached 104° there were only 2 recoveries. No child recovered where the temperature reached 105°. A sudden rise of temperature after operation meant nothing, and was noted in several favorable and several fatal cases. A sudden rise, however, on the third, fourth, or fifth day was a very serious matter, and, with one exception (when it rose 4° on the third day), it meant death. A later sharp rise was noted in four favorable cases in the second week, but it proved only temporary.

There was in no case what appeared to be distinctly diphtheria of the wound, though there were plenty of ugly-looking eroded holes left after the removal of the tube, and three or four cases of cellulitis or erysipelas of the neck. They had no significance. The treatment proved a very interesting part of the cases. A certain part of it was routine, while a certain part was adapted to each case. Every child was taken from the operating-table to a room where the steam-pipes had been tapped, and a cloud of steam was played directly onto the child. Special nurses were detailed to watch the cases night and day, whose duty it was to keep the tube clear by feathers and to remove and clean the inner tube every few hours.

The diet of the cases was milk *ad libitum* and some stimulant, ordinarily brandy; either one or the other of these was given every hour, and in some cases the children were encouraged to take broth and eggnog. The steam was continued until the wound was nearly closed, and the tube was removed on the fifth, sixth, or seventh day, without any preliminary testing. Only two cases had to wear a tube over seven days, and both of these had to wear it for months. Brandy was given in two-hourly doses, and from one to four ounces a day was readily taken. The number of cases is, of course, too small to furnish any very valuable statistics as to the relative value of different treatments, but it is not without significance that in cases treated with corrosive sublimate or calomel the percentage of recoveries was thirty-five, while only twelve per cent. recovered with non-mercurial treatment. The dose of corrosive sublimate was one-sixtieth of a grain every two hours, or every hour in an older child; salivation often followed its use on the second or third day, but was never troublesome after the mercury was stopped. Calomel was more apt to cause diarrhœa, and was given in quarter-grain doses every two or three hours. When diarrhœa or salivation began the mercurial was at once stopped.

The children took on the average from twenty to forty ounces of milk a day; thirty was a fair amount and below twenty was very small. Without regard to age, the children who took the large amounts of milk were the ones who got well. All the recoveries but three were in children who took between thirty or forty ounces of milk daily. In children who took over thirty ounces, the percentage of recoveries was fifty, while in those who took

twenty-five ounces or less, the percentage was only ten. Speaking roughly, the fact that a child was taking its nourishment well was encouraging.

In general, any prognosis, unless the case is a perfectly hopeless one, before the second or third day is largely guess-work. At that time of extremely unfavorable import are progressive glandular enlargement, gummy, or suppressed discharge, and the fact that the child takes less than twenty-five ounces of milk daily. The most encouragement that we can have is an absence of these ominous symptoms, along with a fair general condition of the child.

THE PALLIATIVE OR MECHANICAL TREATMENT OF HERNIA, WITH ILLUSTRATIVE CASES.[1]

With a Brief Report on Repeated Injections of Oak-Bark Without Confinement to Bed.

By W. B. DE GARMO, M.D.,

Instructor in the Treatment of Hernia at the New York Polyclinic.

Through all ages we find voluminous writings on the radical cure of hernia. Every age has had its vaunted cure; still, it remains a fact which we must all recognize, that of all adults suffering from hernia, very few ever obtain a complete and permanent cure. In view of this fact, is it not time that we study those means which shall give the greatest relief to the greatest numbers? that we should strive to secure the afflicted against the dangers which may arise from their hernias, and obtain the greatest amount of improvement possible, rather than endanger their lives in a vain attempt to produce a radical cure?

That very great good shall come from the study of the subject in this light, my past experience proves to me beyond the slightest doubt.

The adjustment of a splint to an insignificant fracture receives the surgeon's most careful personal attention, but in a case of hernia the entire responsibility is transferred by that same surgeon to a mechanic wholly ignorant of the first principles which should govern its proper treatment.

If we attempt to inform ourselves upon this subject by its literature, we will find that there has been the same neglect in the past as now exists. It is almost barren of practical instructions as to how the palliative treatment of hernia should be conducted. If we turn to those books in which we would naturally expect to find something as a guide, we are only told to "put on a good-fitting truss." Just what a good-fitting truss is, we are not informed, and as to the management of the case after such a truss has been applied, it never receives the least consideration.

Necessity, therefore, must be my excuse if in opening this discussion I draw almost wholly upon my own personal experience. The palliative treatment of hernia does not consist of mere truss-fitting; the selection and adaptation of an appliance is only preliminary to the proper treatment of the case. The common habit of prescribing a truss and discharging the patient, cannot be too strongly condemned.

The condition of *every person* suffering from hernia can be improved, but that improvement cannot be accomplished without intelligent care and attention. The patient, after having been supplied with a suitable appliance, must be instructed respecting its correct use, and, as his case improves, the instrument must be altered to meet these changed requirements.

Before speaking of the selection of appliances for special cases, it might be well to say a few words regarding trusses in general; and as there are at the present time fully forty varieties manufactured, these remarks must be generalized.

I am led, from experience, to condemn all trusses without springs, consisting of elastic or inelastic webbing about the body, held in place by perineal bands. Occasionally, for night use, they serve a good purpose, but for day wear I consider them a "delusion and a snare." If the body was perfectly round, they might act well; but being oval, with the most depressed portion in the inguinal region, it is self-evident that the greatest amount of pressure will be exerted where not needed—that is, on each hip. They are a delusion, because they keep the hernia out of sight for a time, but as they leave the upper part of the inguinal canal unprotected, it is quite liable to increase in size until it becomes uncontrollable. The perineal band is constantly drawing the pad down against, or over, the pubic bone.

I object also to all trusses with springs which are applied from the same side upon which the hernia exists. This includes all trusses commonly known as French or German; it includes a large portion of all that are sold throughout the country; it includes what our instrument-makers here call their *best* truss. Best merely because their great-grandfathers made them after the same pattern.

They would have been consigned to oblivion long ago, had the mechanical treatment of hernia been in the hands of professional men. So far as I have ever seen, they cannot be applied so that they will not act as a compress over the pubic bone. I am equally opposed to any truss that has an arm descending from the spring, upon which the pad is carried. A pad so placed cannot be retained high up over the internal ring, and I am positive that to secure the best possible results from mechanical means, that the closing of the upper portion of the canal is an absolute necessity.

As a covering for truss springs and for pads, I have found nothing equal, for cleanliness and durability, to hard rubber. I cannot imagine a better substance, and I know of nothing that is so well borne by the skin.

Before saying anything regarding the truss that I should select for a given case, I desire to speak briefly of the method of fitting which I have followed for the past four or five years; and for so doing, perhaps, a word of apology is needed, as that method has already been published. As its importance may have been overlooked by many at the time, and as I believe it to be the very key which places truss-fitting within the reach of every practitioner, I may be pardoned for again mentioning it.

Any physician who undertakes to treat his cases of hernia will soon discover that, by the ordinary method, it is a very difficult task to shape a steel spring so that it shall be accurately adapted to all irregularities of the form. This fact has prevented many physicians from making more than one or two attempts at truss-fitting.

The method referred to consists in securing a diagram of the outlines of the pelvis. This is traced upon paper, and the spring to be worn is shaped to correspond exactly with this line.

The diagram is secured by means of a lead tape which is moulded to the form in the following manner: One end is placed over the region of the internal ring (for example, we will say of the right side), from this point it crosses the front of the abdomen, around the left hip, to the centre of the back or beyond.

Having moulded this carefully to the form, it is slipped from the body and placed upon a sheet of paper of suitable size.

A pencil tracing of the inner surface of this is made, and the shape of the opposite side taken in the same manner—which, when added to the first, will give the outlines of the pelvis in a fairly accurate manner, as shown in the diagram exhibited.

Any spring that it is desirable to use, can be bent to conform to this line, making, of course, due allowance for pressure. If the spring is covered with leather or celluloid, it may be bent without any preparation. If covered with hard rubber, it must be thoroughly warmed by passing through the flame of a spirit-lamp or gas-jet, before such bending is done.

[1] Read before the Surgical Section of the New York Academy of Medicine, March 8, 1886.

In oblique inguinal hernia of small size I usually select a light spring, which shall cross the front of the abdomen, and around the hip opposite the hernia. I prefer a small convex pad, which shall press just below the internal ring; the object being to close the canal at its origin. It is a very common mistake, even for physicians, to place a truss directly over the external ring. Truss-sellers and instrument-makers always place it there, because there is where they see the swelling, and that is as far as their information extends.

A truss which has been constantly growing in favor with me is a modification of the Hood truss, which supports both sides, even though only one hernia exist. I have had these constructed in several different ways, as you will see on those patients whom I shall show you to-night.

The difference in construction relates more to the strength than to any change in principle. Where the additional expense to the patient is not an important consideration, I think it is always best to use a truss which shall protect both sides. It is quite certain that strong pressure upon one side tends to crowd the abdominal contents toward the other, which produces an unnatural strain upon that inguinal region.

I sometimes use the English pattern cross-body spring, with ball-and-socket pad, which I like very well. I prefer it, however, with a stationary pad, having found that, as a rule, so-called self-adjusting pads shift out of position easier than those that are fastened to the spring. The after-management of an ordinary case of inguinal hernia is, after having it under perfect control for two or three months, to reduce the pressure gradually as the case improves, getting the truss off entirely, if a complete recovery has taken place.

As a class, large scrotal hernias that are reducible are very badly treated. The so-called scrotal trusses of the instrument-makers are a striking illustration of the ignorance displayed in the treatment of these cases.

That they require a very strong truss is frequently true; but that they require a large pad because the hernia is large, is an absurdity.

I commonly select a truss known in the trade as the radical-cure truss, the peculiarity of which consists in the construction of the pad, which has a small, prominent, and hard centre, surrounded by a ring of softer material. This I use until the case is under control, and then exchange for either the Hood or some lighter pattern.

Owing to the shortening of the canal in these old and neglected cases, it is necessary at first that the pad should be placed immediately above the pubic bone, but after the hernia has been retained for a few months, the canal will resume its normal length to such an extent that the centre of pad-pressure may be raised an inch or more. One case briefly stated will suffice to illustrate this class:

A man, sixty-two years of age, was sent to me by the late Dr. Post, with a note saying that he considered the case beyond relief by mechanical means, but to do whatever I could for him, and, if unsuccessful, return him for an operation.

The protrusion was twenty-five inches in circumference, and hung down from the body ten inches. It was on the left side, and had existed for about eight years, without having received any attention. The man was almost wholly disabled for ordinary duties and compelled to abandon his work.

After some difficulty the mass was almost wholly reduced, but the most powerful spring would not retain it for a moment when on his feet, nor for any length of time when in the recumbent position. The man was put to bed for a week or ten days, and the hernia finally brought under control.

The patient is now here for examination. The truss at present worn is of the Hood pattern, which I have recently applied, as I found that he was developing another hernia on the opposite side.

The hernia slips down at times, even now; but there is very great improvement over his previous condition, and he has been enabled to return to his work.

There is one point in connection with this case which I wish to call attention to. When the case came under my care there was a portion of omentum which was not reducible. It was firmly adherent. This has to a great extent disappeared; but I think that those who examine the case will have no trouble in finding the small remaining portion. I call attention to this fact to show that omentum remaining in the scrotum will gradually disappear under pressure of a truss over its neck.

Large hernias should be supported at night as well as by day, but not by the same truss. I sometimes use the elastic truss for this purpose, but more frequently a cushioned, light spring truss. I also present for your examination a gentleman (sent to me by Dr. Bradshaw) who was disqualified for business pursuits by two extreme scrotal hernias. He had tried many things and been the victim of the rupture quacks. In his case the Hood truss had proven very successful. In ordinary examinations it is the custom of many surgeons to pronounce irreducible any hernia that cannot be returned to the abdominal cavity after the use of taxis for ten or fifteen minutes, and the patient is informed that in an operation lies his only hope of relief.

That relief can be afforded these cases, in many instances, without an operation, I have proven to my own satisfaction a number of times, by converting them into reducible hernias, which were controllable by means of a truss. I will cite one case for illustration, and the man is here for examination:

Dr. M. H. Williams sent to me, at the New York Polyclinic, a man about forty years of age, with a very large scrotal hernia, which had existed four years. A truss had never been worn, and not until recently had his hernia given him any trouble.

Of late, symptoms of strangulation had frequently occurred. The bowel contained in the protruding mass was easily reduced, but the greater bulk of the tumor, omentum, appeared firmly adherent, and resisted persistent efforts at reduction.

A truss was adjusted which made strong pressure over the neck of the tumor, and a systematic course of manipulation, which I always adopt in similar cases, was begun. The patient was instructed in making taxis, and was asked to resort to it every night and morning for from fifteen to twenty minutes, while in the recumbent position.

At the end of two weeks the tumor had softened considerably, and before the expiration of one month the patient came to me with his hernia completely reduced. He had worn a truss during the entire time. The case is here for examination. Also another similar one, which is undergoing the same treatment, wherein the hernia has not as yet been reduced, but improvement is already noticeable.

In this manner I have succeeded in reducing four hernias, and by continued pressure of a truss pad over the neck of the tumor I have seen the gradual improvement of several others.

Hernia complicated by a retained or undeveloped testicle is of far more frequent occurrence than generally supposed.

During the past two years I have met with not less than ten such cases, and their frequent mismanagement leads me to speak of them here.

In infancy the delayed descent of the testicle is not uncommonly mistaken for hernia.

Within the past two weeks an infant of six months was brought to my clinic with a truss over a testicle which had just escaped at the external ring. The tumor had been noticed, and the family physician had pronounced it hernia, and sent it to a well-known instrument-maker. The truss being worn was strong enough to retain a large hernia.

Had the use of this truss been continued the testicle would have been kept within the canal, and when the child began to walk a hernia would have developed.

A practising physician of this city came to me, eighteen months since, with left inguinal hernia and a partially developed testicle which could be carried into the canal, where it had been kept for years by the truss worn.

By means of a light truss with a small pad placed just below the internal ring the hernia was perfectly retained, and the testicle was allowed to come outside of the external ring.

I was called to Brooklyn to see a young man, aged twenty-two, supposed to be suffering from strangulated hernia, but found instead an inflamed testicle in the inguinal canal. He had been sent by his physician to a truss-maker, who had produced the orchitis by rude manipulation. No hernia existed, but both testicles were retained in the inguinal canals.

A light pressure over the internal ring will, in such a case, encourage the descent of the testicle and prevent any protrusion through the dilated canal.

A young man now present was sent to me by Dr. W. E. Forest on the 16th of last month, who presented the following condition :

A large scrotal hernia, the contents of which was principally bowel, but containing also from a half to one ounce of fluid.

The fluid as well as the bowel could be returned to the abdomen, leaving just below the external ring a small undeveloped testicle. The history of the case, as furnished me by Dr. Forest, is peculiar. The patient having been subject to attacks of colic, the doctor examined him for hernia. None existed, nor was the testicle outside of the external ring at that time.

Some months later he presented himself with the hernia as already described. The case presents the characteristics of congenital hernia.

The young man is now under treatment by the injection method.

In closing this somewhat disconnected paper, I desire to bring before you a method for which I expect, at a later date, to claim an important place in the list of means at our command for the palliative treatment of hernia.

I expect to make even broader claims for it, as my experience confirms me in the belief that in this method, combined with the skilful mechanical treatment of hernia, we have the means which will afford the greatest relief, and produce the largest number of cures attainable.

I refer to the injection of the extract of white-oak bark into the inguinal canal, in quantities of from five to ten minims, repeated at intervals of about two weeks, and this without confinement to bed, or detention from ordinary business.

The fluid used is after the well-known Heaton formula, and the injection is made into the canal outside the hernial sac.

The patient is first supplied with an accurately fitted truss, which shall retain the hernia as perfectly as possible ; after this has been worn for about one week the first injection is made, and is made in the following manner : With the patient in the recumbent posture, the end of the forefinger of the right hand is passed into the external ring by invaginating the scrotal tissues, the cord and sac being held to the outside of the finger. The forefinger of the left hand is now pressed firmly over the end of the finger that is in the ring, and as the latter is withdrawn, the former is pressed directly into the ring. The needle is passed at the end of the left forefinger directly into the canal, and the fluid gradually deposited. Where the subcutaneous tissues are thin, an ordinary strong hypodermic needle is used, but in cases with a thick deposit of adipose tissue covering the external ring, the hernial syringe described by me in THE MEDICAL RECORD of February 7, 1880, is employed.

Slight discomfort follows the injection, which usually continues for two or three days, and the parts are sensitive for a week afterward. The truss is worn constantly, even at night, if too much discomfort is not produced. As the injections are repeated the truss-pressure is reduced.

I make this preliminary report on this method merely to place it before the profession, that others who so desire may also use it. My first case was treated by this method two years since, and resulted in a complete cure after five injections. I have used it for the past year at the Polyclinic, and with results which warrant my bringing it before you.

I have now in course of preparation a paper on the "Treatment of Hernia by Injection," which will include full particulars respecting this method.

A CASE OF FATAL PURPURA HEMORRHAGICA.

By A. BRAYTON BALL, M.D.,

NEW YORK.

FOR the notes of the following case of fatal purpura hemorrhagica, I am indebted to Dr. S. W. Lambert, Senior Assistant Physician to the First Medical Division of Bellevue Hospital :

J. M——, aged thirty, United States, married, cook, was admitted to my service at Bellevue Hospital, February 6, 1886. Habits very intemperate, but says he has not been on a spree for six months. Within the past few years has had two attacks of acute inflammatory rheumatism. On January 19th he was attacked with pain and swelling in both ankles, but was not confined to bed. These symptoms improved after a few days, but he did not entirely recover the use of the joints. On February 2d his right arm became swollen from the elbow to the shoulder, and soon afterward the left arm was similarly affected, though to a less degree. He lost appetite and felt weak. Twenty-four hours before admission he was seized with a severe cough, with bloody expectoration, which still continues. He had a "chancre" several times, but no specific history can be obtained.

On admission, temperature, 102°; pulse, 124, full, regular. No cardiac murmur or other evidences of heart disease. Lungs normal, with the exception of a few bronchial râles. Liver dulness diminished in extent. Spleen normal in size. External lymphatic glands not enlarged. Urine contains ten per cent. of albumin, granular casts, and blood-cells. On the left side of the neck is a hard, brawny, tender, non-fluctuating swelling, two by four inches in size, which he states made its appearance five weeks ago, and has given him but little annoyance until within the last twenty-four hours, during which time it has nearly doubled in size ; the overlying skin is somewhat reddened, but not ecchymotic ; on exploratory puncture a little blood, but no pus, is obtained. Both upper arms are considerably swollen, and present reddish-yellow ecchymoses of the skin, with tenderness, especially in the region of the elbow-joints. The right hand is also swollen, and the wrist is tender, the skin in the neighborhood presenting some reddish-yellow discoloration. Petechial spots on skin of right eyelid. On the back, loins, and thighs are numerous raised ecchymotic patches, varying in size from that of a pea to that of a bean, together with a few vibices. The tip of the tongue presents an irregularly shaped subepithelial ecchymosis. No hemorragic inflammation or sponginess of the gums. No jaundice.

February 8th.—Hæmoptysis still continues, but is not excessive in amount. Tongue swollen, and of a dark-blue color. Over the hemorrhagic area the epithelium is removed, leaving a superficial ulcer. Subcutaneous hemorrhages on the calves and near the knees, with reddish-yellow discoloration of the skin in these places. Numerous fresh petechial spots are seen on the loins, thighs, and arms. These spots began as raised patches of the

size above mentioned, remaining white for from twelve to twenty-four hours, and then gradually becoming petechial. The temperature has ranged between 102° and 104° F. The albuminuria (ten per cent.) and slight hæmaturia are still present.

February 10th.—The hæmoptysis has ceased. Patient is more comfortable, with the exception of some pain in shoulders and left hand, which is swollen. A few fresh hemorrhagic spots have appeared, especially on left leg. Temperature slightly lower.

February 12th.—Most of the first crop of petechiæ have disappeared, leaving only a slight yellow stain. Fresh eruptions have occurred on loins and thighs. The scrotum is much swollen and of a dark-blue color. Complains slightly of pain in shoulders and elbows. Swelling in neck is somewhat smaller and less tender; no pus obtained on exploratory puncture. Tongue brown, but moist. Temperature, 104° at 1 P.M.; respiration, 48. Examination of heart negative; examination of lungs unsatisfactory. No abnormal physical signs except feeble respiratory sounds and some general impairment of resonance.

February 14th.—Pulse, 150; respiration, 50; temperature, 104°. Dulness and bronchial breathing over right upper lobe, most distinct in right axillary line. Expectoration mucous, not pneumonic. Tumor in neck is diminishing in size. Bullæ have formed on scrotum, which have ruptured and discharged a bloody fluid.

February 17th.—No fresh hemorrhages have been observed. Only a few petechial patches now remain on the skin, and these are of a lemon-yellow color. Appearance of scrotum unchanged. Expectoration profuse and lemon-colored. Pulse, 160, and weak; temperature, 103°. Patient rapidly sank and died at 1.45 P.M. No autopsy was allowed.

The absence of an autopsy in this case makes it difficult to say whether we had to deal with an uncomplicated case of purpura hemorrhagica or whether the hemorrhagic manifestations were due to some underlying condition other than changes in the walls of the blood-vessels. The marked prominence of the joint-symptoms, especially during the last two weeks of the illness, naturally suggests the inquiry whether the case was not, after all, one of acute articular rheumatism complicated with purpura hemorrhagica.

The occurrence of two previous attacks of acute rheumatism is certainly significant in this connection. The joint-symptoms in the present illness, although less intense than is usual in acute rheumatism, were certainly more marked than, and ran a different course from, the joint-symptoms noticed in so-called purpura rheumatica or peliosis rheumatica. In the latter affection the joint-affection precedes the hemorrhages by only a few days, is usually confined to the lower limbs, and subsides when the eruption makes its appearance. In this case the ankles were affected two weeks before any hemorrhagic manifestations.

On February 2d acute articular symptoms developed in both upper extremities, with considerable fever, and continued with but little change until death. Moreover, peliosis rheumatica, as differentiated by Schönlein and others from purpura hemorrhagica, is characterized by the presence of superficial, and the absence of internal, hemorrhages. Still, cases have been observed occasionally which began as a mild peliosis rheumatica preceded by joint-symptoms, and afterward developed into marked or even fatal purpura hemorrhagica with internal hemorrhages, and this fact has led many writers to adopt the view that there is no essential pathological distinction between the two affections. Whether in such cases the arthritic symptoms have ever assumed the prominence noticed in the present instance, I have been unable to ascertain.

Notwithstanding the previous rheumatic history of the patient, and the resemblance of the joint-symptoms in the present attack to those of acute articular rheumatism, there are good reasons, it seems to me, for believing that the arthritic affection was not wholly, if at all, of a rheumatic nature, but was connected with the general hemorrhagic process.

It is to be noted that the joint-lesions were confined to the upper extremities, at least during the last two weeks of the illness, and were situated in the immediate vicinity of extensive superficial and deep hemorrhages. This connection is probably more than a mere coincidence, and points to an explanation of the joint-symptoms similar to that accepted for the joint-symptoms of peliosis rheumatica, viz.: that the arthritic tenderness and swelling were due to hyperæmia and serous transudation or even hemorrhages into the cavities of the joints, these lesions being produced by the same structural changes in the walls of the vessels of the joints as those which underlie the hemorrhagic extravasations in other situations. Again, the development of acute articular symptoms coincided in point of time with the occurrence of extensive hemorrhages into the connective tissue of the adjacent parts.

On the supposition that the joint-symptoms were truly rheumatic, the question naturally arose whether the hemorrhages could be due to a malignant endocarditis which failed to reveal itself by physical signs on the part of the heart. Petechial eruptions have been observed in some cases of this affection, but I have been unable to find any mention of such wide-spread hemorrhages in this connection as were observed in this case; for instance, petechiæ on the left eyelid, hemorrhages into the tongue, scrotum, lungs, kidneys, and probably other internal organs, deep extravasations into the subcutaneous connective tissue of both arms, and numerous petechiæ and vibices on the back, abdomen, loins, and legs. The very multiplicity and severity of these lesions make it highly probable that they were not produced by hemorrhagic infarctions by emboli carried from the heart, but were occasioned by wide-spread tissue-changes in the walls of the blood-vessels.

A word in regard to the high temperature which was noticed in the case. Purpura hemorrhagica is usually an afebrile disease. In the febrile cases, in which the purpuric symptoms are not due to an underlying febrile process, the elevated temperature may be explained partly by absorption from the hemorrhagic foci, and partly by inflammatory irritation excited by these foci. That the febrile disturbance was somewhat more marked than usual in the present case is what might be expected from the great number and extent of the sources of infection and inflammatory irritation.

It may be added that the patient's occupation and habits were such as to predispose him to degeneration of his blood-vessels. The occupation of cook is unfavorable to a proper nutrition of the body. Cooks usually take but little exercise and have poor appetites. The patient's habits were, moreover, very intemperate, and had, most probably, already produced cirrhosis of his liver and kidneys.

The Berlin Treatment of Throat-Disorders.—In the topical treatment of both acute and chronic catarrhal laryngitis and pharyngitis the remedy which the Berlin physicians place before all others, nay, use almost to the exclusion of all others, is nitrate of silver in solutions varying from two to fifty per cent. Moreover, they use the spray almost not at all—instead, make applications with a brush or small sponge. Their theory is that their application is more exact, and touches nothing but the particular portion intended to be touched; but as a matter of fact, except in cases where some growth was to be removed or an application made to an ulcer, the forcible manner in which the brush is moved about in the larynx is almost as injurious as the original trouble. Moreover, their results in catarrhal affections are not as good as ours.—Correspondent of *The Medical Press of Western New York*.

Clinical Department.

HABITUAL ABORTION IN CONNECTION WITH DISEASE OF THE HEART AND KIDNEYS.

Dr. Frank H. Murdock, of Bradford, Pa., writes: On February 9, 1886, Mrs. K——, aged forty-one, came into my office complaining of great weakness, and shortness of breath on making any exertion. She menstruated at fifteen, and has always been regular. She married at twenty, and had six living children at term, all healthy. Then followed four premature births, the fœtus dying about the seventh month of pregnancy, and being expelled four weeks later. Next in order came a healthy living child at term, which was succeeded by five premature births of dead children at the eighth month of pregnancy, the last miscarriage occurring three months ago. Examination of the patient revealed a slight laceration of the cervix, a well-marked aortic systolic murmur, and the urine contained albumen, a quarter, and an abundance of granular and epithelial casts. There is no history of syphilis, and there is now no tenderness over the sternum or tibiæ, and no changes in the retinæ can be detected.

INVERSION OF THE UTERUS.

Dr. George E. Brickett, of Augusta, Me., reports a case of a woman who, on the third day after labor, had severe expulsive pains, and passed a quantity of blood-clots. From that time she continued to suffer from loss of more or less blood every day, was confined to her bed, became extremely emaciated and anæmic, and could not move without shortness of breath, faintness, and vomiting. When Dr. Brickett was called to see the patient, two years later, he found what on first sight seemed to be a polypus, but which a more careful examination showed was the inverted uterus. After a short course of tonic and stimulating treatment repeated attempts were made to reinvert the organ, but these failing, a spring ligature was placed around the base of the tumor, and the uterus dropped off on the tenth day. There was no hemorrhage after the application of the ligature, no severe pain, and no constitutional disturbance. The patient made an excellent recovery, and has enjoyed good health during the seven years that have elapsed since the operation.

A CASE OF IMPERFORATE HYMEN.

Dr. J. G. Knox, of Toomsuba, Miss., writes that he was called to see a young woman, twenty-two years of age, who was supposed to be suffering from gravel, having had difficulty in passing water, and, at the time of coming under observation, was suffering from retention of urine. She was stout, of good color, and seemingly in robust health, but had never menstruated. The abdomen was very large, but no signs of pregnancy were discoverable. A wedge-shaped tumor was found extending obliquely upward and backward from the posterior commissure of the labia to the roof of the vagina. The patient stated that this tumor had made its appearance suddenly while she was lifting a heavy tub of water. The os uteri could not be found after most careful search. A diagnosis of imperforate hymen, with retention of menstrual blood, was made, and the membrane was punctured with a trocar, which gave exit to nearly sixteen pints of a dark, thick, grumous fluid, which, however, had no disagreeable odor. The cavity was then washed out carefully with carbolized water, and the orifice in the hymen was enlarged. The membrane was one-eighth of an inch thick and very tough. The uterus was filled with menstrual blood, and was as large as it would normally be at term.

RUPTURE OF THE LIGAMENTUM PATELLÆ.

Dr. Samuel Thompson, of Toledo, Ia., reports the case of a man, twenty-six years of age, who fell from a wagon, tearing the ligamentum patellæ from its attachment to the tubercle of the tibia. He was supposed at the time to be suffering from a sprain, and was treated by weight extension and liniments. When first seen by Dr. Thompson, three weeks later, he was emaciated, nervous, and suffering great pain in the knee. The joint was flexed to an angle of 45°, the patella was dislocated upward for about an inch and a quarter, and there was a distinct depression just above the tubercle of the tibia. There was very little swelling about the joint, but tenderness and pain on the slightest motion, either active or passive. The patient was discouraged, and was losing flesh rapidly. Dr. Thompson encased the leg in a plaster-of-Paris bandage, pushing down the patella as far as possible and making firm pressure over the knee. The immediate result was an increase of pain, but this subsided in a few minutes, and there was thereafter no pain and great relief from the muscular spasm.

The patient soon commenced to improve in general health, and was out of bed in a week from the time of applying the plaster dressing. The dressing was left on four weeks, and was then removed; passive motion being ordered, to be kept up indefinitely. Dr. Thompson concludes: "Some of the mosaic doctors in this region think, or affect to believe, that the use of the plaster dressing in the case was not the proper treatment. I think it was, for it accomplished what I started out with, viz., to relieve the pain and get the patient out of bed."

A CONGENITAL DEFORMITY.

Dr. H. Hudon, of Fraserville, Canada, writes: On June 10th last I delivered Mrs. M——, at full term, of a male child. The peculiar moaning of the new-born attracted my attention. Upon examination I noticed that the eyes were very small and red. Both ears were entirely absent, their places being supplied by two small cartilaginous lumps. The arms were unusually long, and had no elbow articulations—only one long humerus. The thumbs were absent, and the remaining four fingers were very short. The legs were of the usual length, but were also deprived of the knee articulations. The whole surface of the body was covered with hair, especially on the forehead and face.

Rather Cheeky than Otherwise.—The palm for brazen assurance must certainly be awarded to a new firm of patent-medicine vendors who have taken to sending their circulars and sample bottles of their physic to physicians throughout the country. One of the pamphlets contains a somewhat startling picture of a gravestone. It is not, as might at first sight be supposed, a premium to be given to the consumers of the medicine; but is merely a design of a monument to be erected as a tribute of love and gratitude to the inventor of the sure cure by his patrons, and possibly also as a thank-offering from those who have tasted of the draught and still live. One of the many reasons given why the remedy should be always kept on hand is that it is economical, saving in most cases the expenses of a physician. This is an advantage, as it enables the mourners to pay the undertaker promptly.

A Sceptic.—A gentleman who evidently underrates the value of all previous anatomical study writes to *The St. Louis Medical and Surgical Journal* an account of a wonderful case of intestinal obstruction which he finally cured by passing a piece of rubber-tubing up into the rectum just as long as he could shove it in. He says he "passed nearly two yards of tubing into the resepticle," and excitedly exclaims, "What I want to know *is* there such a thing as the illiasecle valve?"

Progress of Medical Science.

TREATMENT OF CHOLERA BY ABDOMINAL COMPRESSION.—Dr. C. Bruckner writes in *Memorabilien*, xxxi., No. 8, to direct attention anew to a therapeutical measure employed by him successfully in the cholera epidemic of 1872. The excessive loss of fluids from the intestines and stomach causes an inspissation of the blood, in consequence of which the circulation is markedly impeded. The nutrition of the tissues, and especially of the intestinal nerves, already partially paralyzed by the contagium, is thus so seriously interfered with as to constitute in itself a special menace to life. The author was thus led to discontinue all medication, the blood stasis rendering absorption in most cases impossible, and sought to compress the abdomen by means of a cold sand-bag, weighing from nine to fifteen pounds, such as is sometimes used in uterine hemorrhage after parturition or abortion. By means of this combination of pressure and cold (ice was also given internally), he states that not only were the intestinal discharges controlled, but the circulation was improved. When the pulse showed that circulation was again active, the remedies deemed appropriate could be administered with every hope that they would act promptly. Dr. Brückner employed this method in twenty-five cases of cholera at different stages, and lost but three patients. His papers were published in the *Deutsche Klinik* for 1873 and 1874. He advises, as a more effective mode of producing compression, the application of an elastic band around the body; between this band and the abdomen are placed two metal plates which can be separated by means of a screw. In this way any desired amount of compression can be obtained, and at the same time the application of cold is facilitated by placing the ice-bag between the two plates. Professor Kashimura, of Japan (*Wiener Medizinische Presse*, No. 42, 1885), employs a somewhat similar principle, placing large ice-bags on the abdomen. But the degree of compression obtained is much less by this method than by that just detailed.

OTALGIA.—This is the title of a recent memoir by Dr. V. Grazzi. The author treats only of those forms of earache which are nervous in their origin, and not due to any inflammatory conditions. Nervous otalgia, he states, is due to an alteration in the sensory nerves distributed to the external, middle, or internal ear. Neuralgia of the pavilion is rare, and usually circumscribed; if the pain is seated in the anterior aspect the auriculo-temporal branch of the fifth nerve is affected; if on the posterior surface the superior cervical. Earache is often reflex in its origin, depending upon dental caries, ulcerations of the epiglottis, lesions of the larynx or pharynx, cancer of the upper portion of the œsophagus, etc. Malarial poisoning is also an occasional cause of otalgia. The author has several times seen it arise with the paroxysms of fever, and subside as these passed away. Rheumatism, hysteria, and sudden atmospheric changes may also occasion pain in the ear. The chief symptom is pain coming on suddenly, usually in the night, then subsiding and returning periodically. In neuralgia of the pavilion a light touch often aggravates the pain, while temporary relief is sometimes obtained by strong compression. The pain of otalgia is increased by passing from a warm to a cold atmosphere, and loud noises or words spoken close to the ear may induce a fresh attack. The auditory sense is sometimes blunted. The affection may last several days or weeks, and may become chronic, especially if the causal conditions remain unchanged. The best remedy, Dr. Grazzi states, at the beginning of an acute attack, is valerianate of quinine, with which may be combined iodide of potassium, as recommended by Politzer. In the chronic form, the best results have been obtained from the continued current; the positive pole is to be placed in the ear and the negative pole applied to the nucha. The induced current is contra-indicated. Pain caused by lesions of the middle ear may often be relieved by the insufflation through the Eustachian tube of the vapor of chloroform or turpentine.—*Revue Médicale*, February 6, 1886.

THE TREATMENT OF ACUTE PROSTATITIS BY HOT WATER INJECTIONS.—M. Paul Reclus speaks very highly of the value of hot rectal injections for the relief of the pain and turgescence of the prostate in acute inflammation of this gland. He uses water at a temperature of 130° F., and instructs the patient to retain the injection as long as possible. At the same time he applies wet compresses of the same temperature to the perineum. By this means he states the pain is almost immediately relieved, vesical tenesmus and dysuria disappear, the swelling diminishes, and a complete cure is obtained within a few days. He relates two cases, one the result of gonorrhœa, in a man thirty-one years of age, and the other in a man of fifty-five years, in whom an acute prostatitis supervened upon a chronic enlargement of the gland. In both cases the relief obtained by the use of hot injections and perineal compresses was almost instantaneous.—*Journal de Médecine*, January 15, 1886.

A WAY OF LIMITING THE MISCHIEF OF POLITZER'S METHOD TO A SINGLE EAR.—In unilateral aural affections the employment of Politzer's and other similar methods often causes injury to the healthy ear, the drum membrane of which, stretched violently outward, carries with it the chain of ossicles. And sometimes, when there is obstruction in one Eustachian tube, the full force of the inflation is expended upon the ear which requires no treatment. The practice of stopping the healthy ear with the finger is an ineffectual means of averting this inconvenience. At the third International Congress of Otology, Dr. Loewenberg exhibited an apparatus designed to correct this fault. The tube attached to the air-bag is divided into two, the end of one being placed in the nostril in the ordinary way, that of the other in the meatus of the sound ear. When the bag is compressed, the air-pressure tending to force outward the membrane of the tympanum is met by an opposing column of air from without, of equal force, so that between the two currents the equilibrium of the membrane is maintained.—*Lo Sperimentale*, January, 1886.

THE TREATMENT OF FEVER BY ELECTRICITY.—Professor E. De Renzi, having by chance observed a case of quartan fever cured by the application of electricity, instituted a series of experiments in this direction, and has formulated as a result of these observations the following conclusions: 1. Fevers of malarial origin resist the action of the electrical current much more than do those symptomatic of bronchitis, pulmonary phthisis, etc. 2. During the application of electricity the temperature remains elevated, or even rises a fraction of a degree; but soon after, at the most within an hour or two, a fall of several degrees occurs. 3. The best effect is obtained by holding a moist electrode in the hand while a metallic brush attached to the other pole is swept over the surface of the body. 4. Arterial pressure is increased during the application, the skin becomes reddened and often moistened with perspiration, and the pulse is increased in force. It is probable, therefore, that the antipyretic effect of electricity is due to the increased activity of the cutaneous capillary circulation, whereby caloric is more rapidly lost. —*Gazzetta Medica Italiana*, January 23, 1886.

SPASTIC SPINAL PARALYSIS.—Dr. Gaetano Zavena relates the case of two individuals of the same family—father and son—who were attacked nearly simultaneously with a peculiar paresis of the lower extremities, the symptoms being those of spastic spinal paralysis. No cause could be found for the trouble except that both men had been living for two years on an almost exclusive diet of French or kidney-beans. The author was led to suppose the existence of a nervous alteration due to the bean diet, similar in its nature to lathyrism.—*Raccoglitore Medico*, February 10, 1886.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 3, 1886.

LIFE AS A PUTREFACTION.

THE conviction has been growing that the evil effects produced in the animal system by the action of micro-organisms result from certain chemical poisons developed during bacterial growth. It is very well known that there are always produced in the putrefaction of tissues certain toxic substances which are known as ptomaines. Some peculiar ptomaines, resulting from the activity of special bacteria, may, it is thought, give rise to a special disease. The symptoms of cholera, for example, are supposed by some to be due to those alkaloidal products of the growth of the cholera bacillus. It has long been suspected that certain putrefactive products were the cause of certain morbid symptoms, such, for example, as those of dyspepsia in disease of the stomach or of fever in gastro-intestinal catarrh.

The view, however, that in the natural and normal course of tissue activity there are any poisonous alkaloids developed must be considered somewhat novel. A French contemporary, which apparently has access to the sibyllic books, tells us that the principal medical event of this year is certainly the communication which M. A. Gauthier has made to the *Académie de Medecine* upon ptomaines and leucomaines, in which he announces the discovery that in normal vital action there is a continual manufacturing of poisons, which, if not eliminated, cause disease. The comment of Professor Peters is quoted: "Can the medical mind hesitate a moment between the parasitic doctrines, full of shadowy hypotheses, and this new doctrine, as luminous as it is precise, which explains the phenomena of normal and abnormal life by life itself in action?"

Has some one then opened the door to a New Pathology?

M. Gauthier tells us that he has found in the excretions of living animals, healthy as well as diseased, bodies of the nature of ptomaines. The alkaloids of the urine described by Liebreich and Pouchet belong to this class. Recently he has also discovered in the muscular juice five new alkaloids, "perfectly defined and crystallizable;" these latter have a more or less powerful action upon the nervous system, producing somnolence, fatigue, and even vomiting and purgation, having, in fact, an action similar to but milder than that of the cadaveric alkaloids. This group of substances is called leucomaines, from λεύκωμα, white of egg, and they are defined as alkaline bases appearing during life in the tissues and derived from the albuminous matter of the tissues.

To establish the fact that life is in part a kind of putrefactive process, Gauthier makes some calculations showing that part of the vital processes is "anaërobic," *i.e.*, takes place without the aid of oxygen. According to certain experiments of Pettenkofer and Voit, a dog weighing 33 kilos absorbs daily 477 grammes of oxygen in the form of air, and excretes 587 grammes, or an excess of oxygen averaging 110 grammes. This excess represents a breaking up of tissue and yielding up of its oxygen; it is not a combustion, like the larger part of vital processes, but a putrefaction, such as the micro-organisms produce, It is, therefore, assumed that one-fifth of tissue metabolism is "anaërobic," or putrefactive, and leucomaines are the result. We already know, says Gauthier, that our bodies are constantly developing and discharging such putrefactive products as ammonia, carbonic acid gas, sulphuretted and phosphuretted gases, indol, scalol, phenol, fatty acids, etc. We may be perfectly prepared to expect, therefore, that there should be putrefactive alkaloids, smaller in amount, more powerful and insidious in action, in the secretions, blood, muscles, and other tissues.

Many diseases may result from imperfect excretion of these leucomaines. Indeed, there would be a continual auto-infection from them if the skin, kidneys, bowels, and lungs did not act freely, and the oxygen of the blood, which is their great enemy, were not continually supplied to the tissues. Whether any specific diseases may result from the accumulation of certain leucomaines in the system remains to be determined. MM. Gauthier and Peters believe that here is a fruitful field for further research. They may be right, but we may remind our readers of the researches of Guareschi and Mosso, who showed what serious sources of error there are in experiments to determine the presence of ptomaines and leucomaines. They found residue having alkaloidal reactions in alcohol, ether, and chloroform, while in ninety-six pounds of human brains they found only a minute quantity of toxic alkaloid. Leucomaines, if they exist, therefore, are apparently only in extremely minute amount.

THE GERM OF TYPHOID FEVER.

MICRO-ORGANISMS were found in the blood of typhoid-fever patients more than twenty years ago, and experiments to determine their significance have been going on ever since. The results, until lately, have not been very fruitful. Previous to the careful studies of Gaffky very little real advance was made owing to the imperfection in technique. Gaffky made a series of pure cultures of the bacillus of typhoid, after the method of Koch. He found the bacilli in twenty-six out of twenty-eight. They were observed in the mesenteric glands, spleen, liver, kidneys, and swollen follicles. Pure cultures made upon potato and gelatine were inoculated into lower animals with negative results. Hence, although the typhoid bacilli were found only in that disease, Gaffky obtained no positive evidence of their pathogenetic function.

Subsequent experimenters have been more fortunate. In a recent monograph by E. Fraenkel and M. Simmond, some successful inoculation experiments are reported. Still later, Professor A. Fraenkel, in the *Centralblatt für*

klinische Medicin, March 6, 1886, contributes the results of his experience. He made pure cultures of the typhoid bacteria obtained from the spleens of four different cases. These cultures he injected into mice, rabbits, guinea-pigs, and doves, using from three to five minims of the gelatine culture-fluid. Of the sixteen mice, all died, and were found to have enlarged spleen and swollen Peyer's patches, while the characteristic bacilli were found in the blood. The inoculated doves were refractory, while of three rabbits only one died. The autopsy upon it was practically negative.

The guinea-pigs, however, which did so much for the scientific habilitation of the cholera bacillus were equally useful in the present issue. The virus was injected directly into the duodenum, as in the case of the cholera bacillus. The animals died in from five to seven days. On post-mortem examination, no peritonitis existed, but the spleen was found enlarged, Peyer's patches throughout the intestine were swollen, and one of them actually ulcerated. The mesenteric glands were also swollen. The characteristic bacilli were found in the intestinal wall and the spleen. Sometimes slight capillary hemorrhages in the bowel were noticed. Fourteen animals were experimented upon, of which seven gave positive results. Of these seven, five received the virus directly into the duodenum, while in two it was injected subcutaneously.

Fraenkel tried some experiments with mitigated virus, *i.e.*, virus enfeebled by growth at a high temperature. In six injection experiments in which the fluid was deposited in the duodenum the results were negative, showing that the bacilli can by culture be deprived of their potency.

The experiments of Fraenkel and those of E. Fraenkel and Simmonds furnish decided progress in the work of showing that the typhoid bacillus is the specific germ of typhoid fever.

THE CAUSE AND PROGNOSIS OF CEREBRAL APOPLEXY.

The unfortunate illness which has attacked Secretary Manning calls attention to some of the facts which the modern pathologist has developed, or is still studying, with regard to the subject of cerebral hemorrhage. One fact which the pathologist has not perhaps felt called on to investigate is the apparent increase, relatively and absolutely, of this trouble. In England and Wales, during the years 1850–54, the average annual death-rate from apoplexy per million inhabitants was 454.2, while in 1870–74 it was 523.8. During the same periods the ratio of deaths from brain diseases increased from 192.4 to 248.6.

In New York City the total deaths from apoplexy and hemiplegia in 1874–75 amounted to 1.35 per cent. of the total death-rate; in 1884 the percentage was 1.8. Even bearing in mind the fact that more persons reach the apoplectic age now than did thirty years ago, it still remains probable that apoplexies are on the increase.

Modern pathology has shown that the primary cause of cerebral hemorrhages is, in the great majority of cases, the bursting of miliary aneurisms which have developed on the cerebral vessels as the result of a local periarteritis. The most important supplemental cause to this is an increased arterial tension due to heart disease, plethora with corpulence, and disease of the kidneys with the arterial sclerosis often accompanying it. Charcot found hypertrophied heart in forty per cent. of cases of cerebral hemorrhage, and renal disease in 32½ per cent.

The cause of the miliary aneurisms is naturally the point that should most interest the physician, but here little progress has been made. We know in general that they develop almost solely in persons passed forty, while from fifty to seventy is the apoplectic age. As in five-sixths of the cases atheroma of the arteries is present, we may attribute the aneurisms to much the same cause as the atheroma, viz., degenerative changes natural to old age, chronic alcoholism, specific disease, and continual excesses and exposure of almost all kinds. They develop more often in men, and heredity, as shown by Hughlings-Jackson and Dieulafoy, undoubtedly plays its part.

It is still a matter of some doubt whether such a thing as the "apoplectic habit" exists. Most systematic writers of late years deny it, but it is very evident that many of these authorities either "speak by the book" or argue from a hospital experience among the poor, who do not suffer from corpulence. We are ourselves much inclined to side with Immermann, who places apoplexy among the prominent "complications and sequelæ" of corpulence, especially if with it there is plethora. A corpulent man who has passed the age of fifty is more likely, other things being equal, to have degenerated arteries and higher arterial tension than a spare man. He is in more danger of an intracranial hemorrhage.

Brain-workers are not by virtue of their work made liable to apoplexy. This is a disease of nutrition and of the blood-vessels; its causes are senility, exposure, and intemperate living in the broadest sense. Whatever puts off old age delays degenerative changes and lessens also the tendency to apoplexy.

The prognosis after an attack occurs relates to life and to health in the future, should life be preserved.

Quick onsets, quickly recovered from, are more favorable than those coming on slowly. When the attack comes on without loss of consciousness, as was the case, we are told, with Secretary Manning, the prognosis *quoad vitam* is very good. If loss of consciousness is profound, and lasts twenty-four or forty-eight hours, the outlook is most ominous. But one of the worst prognosticators of the future is the clinical thermometer. A progressive rise or a steady fall of temperature means death, while an absence of rise or fall of temperature is a most favorable sign. The extent of the paralysis, and aphasia, if that exists, gives a fair indication of the extent of the lesion, and this, in connection with a history of its progress during the first fortnight after the attack, will tell how much of mental or physical restoration can take place.

THE NEW HAVEN WATER-SUPPLY.

We have received from Professor Herbert E. Smith and Mr. William E. Lockwood, of the Medical School of Yale, some criticisms regarding the reports upon the water-supply of New Haven. These criticisms relate especially to the analyses of this supply made by Dr. Arthur J. Wolff, of Hartford, and published officially in the Report of the Connecticut State Board of Health.

Dr. Wolff's figures make the water of New Haven worse than it really is, according to Professor Smith and others. There is also a peculiar uniformity in the figures.

From three of the four sources of the water-supply Dr. Wolff's analyses give as follows: Total solids, 17.6 to 19.1 grains per million; chlorine, 7 grains per million; ammonia, free, .011 to .05 parts per million; ammonia, albuminoid, 0.100 to 0.341 parts per million.

In contradiction to these figures are those of Professor Smith and his assistant. These authorities make the total solids from 2.5 to 4.6 grains per gallon, while the chlorine does not reach above 4.79 parts per million, instead of 100 to 105.7, as given in the State Health Board's Report. Very similar results were obtained by Professor R. H. Chittenden, whose figures are quoted by Professor Smith, and who finds only one-sixth as much "total solids" as did Dr. Wolff. Samples of the same supply, as our correspondents believe, were examined at the same time by Dr. Wolff and Professor Smith with the following very different results:

	Total Solids.	Chlorine.	Ammonia. Free.	Albuminoid.
Dr. Wolff	305.	105.7	0.0173	0.276
Authors	59.9	4.8	0.034	0.108

THE SUCCESSFUL RESECTION OF FIVE FEET OF INTESTINE.

It is, we believe, only about four years since the gangrenous gut in strangulated hernia has been successfully resected by a primary enterorrhaphy. In 1884, Baum, of Danzig removed 137 ctm. by a primary operation, but the patient died. Koberle has successfully removed two metres of the intestine by a secondary operation.

Recently Professor Th. Kocher, of Bern (*Correspondenz Blatt*, March 1, 1886), reports a case in which he successfully resected 1 metre 60 ctm. of gangrenous intestine. As this, according to his statement, is the first time in which so large a portion of the intestine has been successfully removed in strangulated hernia with gangrene, the case deserves some notice.

The patient was a laborer, fifty-seven years of age, and for years had had a right-sided inguinal hernia of about the size of an egg. He was brought into the hospital while suffering from a strangulation of the gut that had lasted about twenty-four hours. An operation was deemed necessary, and upon cutting down into the sac the intestine was found plainly very œdematous and gangrenous. On account of the extensive gangrene it was decided to resect the intestine rather than leave it. This was accordingly done, under careful antiseptic precautions; thirty vessels in the mesentery had to be ligatured. The wound was closed and a drainage-tube inserted; the patient was fed mainly by the rectum for three days. The wound healed without any reaction or complication, and the patient was discharged, perfectly well, in eighteen days. He was seen again in the fall, and reported that he had never been better in his life.

Kocher makes a number of interesting comments upon this case. He explains the mechanism of the sudden strangulation by the extremely high pressure in the sac. This reached 67 ctm. of water, while the pressure in the mesenteric veins is only about 40 ctm. of water, hence stasis of the blood, œdema, and gangrene.

The question in this case arose as to whether there should be a resection, or whether the parts should be left to form an artificial anus. In Kocher's opinion the conditions forbade the latter plan. The statistics of Heimann (83 cases), gave for the operation for artificial anus a mortality of only five per cent., while the statistics of Guillard (44 cases), and Madelung (88 cases), make the mortality for intestinal resection about fifty per cent. Kocher, however, takes a much more gloomy view of the future of patients who are left with an artificial anus, and thinks that a great part of them die of malnutrition or some intercurrent disease of the bowel. Kocher, therefore, on these grounds, and on the ground of the greater safety of enterectomy under careful antisepsis, makes a plea for the more frequent application of this operation in cases of strangulated hernia with gangrene.

AN HONOR TO DR. SAYRE.

It has often been cited as an argument against the dignity of the Republic, that although we call ourselves Americans, we are in truth but a mongrel race, tracing our progenitors to the back stairs of every European nation. During the early stages of our development, and even at the present day, there is something of truth in the accusation; and yet there are many and mighty indications of occult sub-currents in our unique society tending ever to a higher and more homogeneous civilization. Naturally, in the process of welding men to the heart of the Republic, forces have been liberated which, up to a comparatively recent period, found expression in material creations of the most gigantic and unheard-of dimensions. Pending these struggles science and letters were necessarily neglected. But there has come a change upon us. To-day we have undoubtedly a literature which reflects to a certain extent the genius of the American mind; and in science we have opened pathways leading to ends so practical as to cover a positive industrial revolution. It is but natural that this reflection of our environment, this "spirit of the times," this Americanism should have found expression in medicine. We are not surprised, therefore, to find that there has grown up on this side of the Atlantic a medical literature, the most striking characteristic of which is its practicality. This characteristic of American medical writers seems now to be universally recognized in Europe. A notable instance of this is seen in a recent German translation of Dr. Lewis A. Sayre's "Lectures on Orthopædic Surgery." The translator, Dr. F. Dumont, of Berlin, draws, in the preface to his translation, especial attention to the practical attributes of the American mind. He instances this quality as the reason why they have succeeded so well in the domain of orthopædic surgery. As Dr. Dumont truly observes, the name of Sayre is too well known in Europe to require an excuse for the present translation. We heartily congratulate Dr. Sayre upon the well-deserved honor, which is alike a credit to himself and his countrymen.

A New Surgical Specialty.—*The Weekly Medical Review* announces that it will have a special department on Railway Surgery. We are told that the number of cases treated in the hospitals of the Missouri Pacific system alone, during one year, was over one hundred thousand, and that that system employs one hundred and forty-nine surgeons.

News of the Week.

Miami Medical College graduated a class of forty at its Commencement on March 11th.

The Medical College of Ohio held its sixty-sixth Annual Commencement on March 10th, and graduated a class of seventy-eight.

American Climatological Association.—The third annual meeting of this association will be held in Philadelphia, on Monday afternoon and on Tuesday morning and afternoon, May 10 and 11, 1886. Contributions have already been promised by Drs. Loomis, of New York; Garland and Bowditch, of Boston; Baker, of Lansing, Mich.; Pepper and Osler, of Philadelphia, and others.

The French Surgical Congress will hold its second meeting at Paris from October 18th, to October 21st. The subjects contained in the programme are: Nature, Pathogenesis, and Treatment of Tetanus; Nephrotomy and Nephrectomy; Orthopædic Resections; Surgical Operations in Irreducible Dislocations. Papers on other subjects cannot be read at the Congress unless the conclusions of the authors are forwarded to the secretary, Dr. S. Pozzi, 10 Place Vendôme, Paris, between July 1, and July 13, 1886. Papers that are not read will not be printed in the Transactions.

The Medical Society of the State of Tennessee holds its next annual meeting at Memphis, beginning April 6th.

The Kentucky State Medical Society holds its thirty-first annual session at Winchester, June 23, 24, and 25, 1886.

Such is Fame.—A Western medical journal with one stroke of the pen emasculates and crushes an esteemed townsman. It says that the new National Association of Physicians and Pathologists is to meet under the presidency "of one *Frances* Delafield."

The National Board of Health.—Efforts are now being made in Washington to restore to the National Board of Health those powers of which it has been stripped, and which when it had them made it a very efficient body. We all know that to accomplish much good from a sanitary point of view we must have concerted action; we must have organization, harmoniously working, all the way from the national down to the county or township or village Board of Health. Duties that properly belong to the National Board of Health have been, for some occult reason, relegated to another department of the Government, and it is the effort to restore this power to its proper place to which we refer. For this praiseworthy effort we bespeak the influence of our readers, and ask them to urge upon their Congressmen the importance and justice of the measure.

The Amount of Solids which should be present in milk in order to have it approach a normal standard is shown by the results derived from an examination into the milk product of Massachusetts, completed by the department of health of the State Board of Health, Lunacy, and Charity. The milk examined was selected from herds, individual cows, and from cows owned by public and private institutions, all the samples being of known purity, as the inspectors were compelled to witness the milking of the samples gathered. The average solids of all samples of milk obtained from private farms, from herds, and single cows, 426 in all, was 13.36. This amount may be compared with the average amount of solids from samples obtained from all sources, 601 animals, which was 13.26. These two statements represent the average quality of the milk produced by the 150,000 cows of Massachusetts.

What Chicago is Doing for the Profession.—Homœopathy seems to be thriving at the stronghold of the Old Code. In the last six weeks two regular colleges have graduated 243 students, while two homœopathic medical colleges graduated 167. There is another regular college to be heard from which generally graduates about forty, and an eclectic college which graduates about fifty. The total annual output of regulars, therefore, is about 285, and of irregulars about 215. Of the 641 eclectic and homœopathic graduates in 1884, over two-thirds (476) were graduated from Western and Southern colleges.

Delegates to the American Medical Association.—The rates given to the delegates to the American Medical Association, meeting May 4th, in St. Louis, have been fixed by the different railroad committees of the country at one and one-third fares for the round trip. Delegates must pay full fare coming, and will receive, on application, from the agent at the starting-point, a certificate which, when signed by the Chairman of the Local Committee of Arrangements, will entitle them to the reduced return rate.

Acute Coryza is a Neurosis, according to Dr. Lees, of London, and is best treated or cut short by the following method: From forty to sixty grains of bromide of potassium were given at once, the dose being repeated in six hours, and again, if necessary, six hours later; and twenty drops, equal to fifteen minims, of tincture of belladonna were also given every hour or every two hours, until the throat felt a little dry. Painting the nasal mucous membrane with a four per cent. cocaine solution gave great relief, and might even by itself suffice to arrest a cold.

The Importation of Rags.—The Local Government Board in London and the Board of Supervision of Scotland have extended the prohibition of the importation of rags from Spain until May 1st.

Fees for Medical Expert Testimony.—Dr. F. G. Groner, of Big Rapids, Mich., writes to the *Medical Age* that in the case of the People *vs.* Vanimmens a physician was called to testify on behalf of the defendant, and when asked for a professional opinion refused to answer until a fee for expert testimony was secured. The judge said he had no authority to secure the fee; the bill must go before the Board of Supervisors. Witness said he had had enough experience with that body to trust them no further. The judge said this question has never been decided in this State. "I can insist," he said, "on the witness answering, and if he then refuse I can fine him for contempt of court, and then let him fight it out with the Supreme Court. But after many years' study and

observation, I decide that a physician's knowledge is his stock in trade, his capital, and we have no more right to take it without extra compensation than we have to take provisions from a grocery without pay to feed the jury. The Court rules that the witness is not *compelled* to testify." The doctor at once stepped off the stand. The defence took exception to the ruling of the Court. Should a new trial be granted, this will be one of the points to be decided by the Supreme Court.

The Southern Medical College held its Annual Commencement at Atlanta on February 25th and graduated a class of thirty-four.

The Medical College of Indiana graduated a class of twenty-nine at its recent Annual Commencement.

The Central College of Physicians of Indianapolis graduated a class of twelve at its last Commencement.

Injuriousness of Natural Gas as a Fuel.—It is thought by some physicians in Pennsylvania, says *The Sanitary News*, that the use of natural gas as fuel is responsible for many cases of diseases of the respiratory organs. The manner in which it is burned in grates necessitates almost entire closing of these important means of ventilation, and the burning gas also vitiates the air of the room with products of combustion.

The Question of the Disinfecton of Rags has come up at Boston, owing to the protestation of the importers against the restrictions of the Health Board. The views of several experts to whom the matter was referred were expressed as follows: First, that the treatment of rags from non-infected ports is not necessary. Second, that from endemically infected ports rags (1) be disinfected to the satisfaction of the Board of Health before embarkation; or (2) disinfected externally in bulk at the port of entry, and also at the mills after breaking bales; or (3) disinfected after imbaling at the port of entry at the discretion of the Board of Health. Third, that from epidemically infected ports the importation of rags be prohibited. Some evidence was given to show that the superheated steam process did not in practice always raise the temperature to a point sufficient to kill the germs.

Creation of a Fund for the Encouragement of the Experimental Cure of Phthisis.—Professor Verneuil, of Paris, has started a fund for the purpose of enabling experimental studies in the treatment of tuberculosis to be carried on. M. Verneuil seems to think that it may be possible to prevent the development of phthisis after contamination by some inoculation method similar to that employed by Pasteur against rabies. The project of securing a fund is enthusiastically supported by the *Gazette Hebdomadaire* and by Dr. Landouzy in the *Revue de Medecine*. Phthisis alone killed sixty-five thousand five hundred and sixty-three persons in Paris during five years.

The Weekly Medical Review wisely discourages the somewhat factious spirit displayed in some quarters as regards the next meeting of the American Medical Association. It says: "The object of the Association is to advance medical science and formulate professional opinion in the United States. Its present most important duty is to provide for the coming of the Medical Congress. Is this object to be attained and this duty discharged by fomenting sectional strife?"

Another Death from Chloroform.—The intelligence reaches us that another death has occurred from chloroform at the outset of preparing an adult patient for a surgical operation. It is the old, old story, which has been repeated so often that it ceases to make any impression upon the stolid adorers of sulf-sufficiency. This time the "accident" occurred in the private hospital of a competent surgeon, in this city, who evidently has failed to see the handwriting upon the wall, so plain that it has been read by all except the indifferent and the stoical.

New York City Lunatic Asylum.—Dr. T. M. Franklin, Medical Superintendent of the New York City Lunatic Asylum, Blackwell's Island, has tendered his resignation, which has been accepted, to take effect on May 1st next.

Dr. James R. Leaming.—We learn that Dr. Leaming has resigned his Professorship of Medicine at the New York Polyclinic.

Obituary.

SAMUEL WARD FRANCIS, M.D.,

NEWPORT, R. I.

The death of Dr. Samuel W. Francis, of Newport, R. I., on March 24th, will cause the keenest sorrow and regret among his wide circle of friends. Dr. Francis had done much literary and scientific work during the twenty-five years of his professional life, but of late had confined his activity mainly to the sanitary and medical interests of Newport.

Dr. Francis was born in this city in 1835. His father, Dr. John W. Francis, was for years one of the prominent figures, socially and professionally, in the history of the metropolis. Having received a degree from Columbia College in 1857, Dr. Francis entered the University of New York, from which he was graduated as a physician in 1860. He distinguished himself while a student by taking the Mott prize medal for the best record of clinics at the University. The first two years of his professional life were passed here as physician in cases of diseases of the head and abdomen at the New York Dispensary in 1860 and 1861, and physician at the same place of diseases of the skin for the following year. While so engaged he wrote a medical essay on "Water," which commanded attention. He went to Newport in 1863. For twenty years or more he was identified with the various interests of that city. He was among the early advocates of sanitary reform, and materially aided in organizing the Sanitary Protection Association, which was the first step which led to the forming of a Board of Health. He was the originator of Newport's Natural History Society, and was interested in the medical society and in various charitable and benevolent organizations. He wrote several books, among them "Inside Out," "Biographical Sketches of Distinguished Living New York Surgeons," "Biographical Sketches of Distinguished Living New York Physicians," "Life and Death," "Curious Facts Concerning Man and Nature," and "Invention of Transparent Treatment." He was ingenious and devised many improvements in methods of treatment, patenting twelve inventions. The New York Academy of Medicine, the New York Historical Society, of which he was a life-member, and the Rhode Island Medical Association were among the organizations with which he was connected.

Reports of Societies.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 5, 1886.

BEVERLEY ROBINSON, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT presented an improved form of *galvano-cautery*, with different forms of points.

THE PRESIDENT also presented a patient who illustrated

REFLEX OCULAR SYMPTOMS IN NASAL DISEASE.

The young woman had been treated for an affection of the eyelids by Dr. Loring, who had also prescribed spectacles for her. At the same time she complained of more or less disturbance in the nasal passages, and on examination Dr. Robinson found a number of exceedingly sensitive areas, especially in the left nasal fossa, which corresponded to the eye most affected while she was under Dr. Loring's care. These areas he had touched twice with the galvano-cautery, employing the apparatus exhibited to the Society. The first application was made three weeks ago, the second about ten days ago, and the patient stated that she was almost completely relieved from both nasal and ocular symptoms.

AURAL HALLUCINATIONS.

DR. SAMUEL SEXTON brought before the Society a case of aural hallucinations which he believed would be of interest, since the relations of *tinnitus aurium* to mental disease was liable to be overlooked, and it was probable that in some cases, where the cause of these fancied phenomena could be explained, it would allay nervous excitement. The patient is an Irishman forty years of age, who states that he has long been of intemperate habits. He has been subject to "dry throat" in the morning, to frequent headaches, and is nervous and "shaky." He stated, when he came to the New York Eye and Ear Infirmary in December, 1885, that seven months previously, after a severe "spree," he had delirium tremens, and on recovery experienced annoying sounds in the left ear; persons either seemed to be "talking to him constantly" or there were sounds of voices in this ear. At first he thought the voices heard were those of persons following him about "for the sake of a joke," but of late he believes they may be due to some disease of the ear. As regards the tinnitus, he describes a "beating" sound in the ear synchronous with the cardiac pulsation, and a "buzzing." Sometimes there is low whistling. There has been no annoying disturbance in the left ear. The utterances heard are always profane or otherwise bad, and on "giving himself up" to the delusion he believes himself to be the subject of abusive language. When he himself is not directly the subject of invectives, he is still cognizant of a colloquy between two individuals on some other topic. He cannot escape from these unbidden defamers at will, but sometimes the noises in his head are less pronounced, and then the hallucinations are also less marked. At such times he is less worried, and feels as though he "could control himself" and throw the delusions off. There are times, however, when the voices do not din so unceasingly in the ear, but then he finds himself annoyed by knocks upon his door and steps in the hall; these sometimes arouse him up out of a semi-unconscious state with a shock. He often fancies "a party in the house is playing a game on him" with an electric battery; he can hear it "click," and "it nearly shakes him out of bed, and plays on his head like a hose." Then he is annoyed by speaking and whistling through a gas-pipe or tube coming up through the floor. Sometimes he "feels a kind of dizziness through the head." He has been to a police station about this trouble. He says the "voices" always remain outside the door. One of the "voices" is a heavy "bass" voice, the other is "high and squeaky," and may be a woman's or a boy's; they are comparatively as a "tin whistle to a cornet."

The patient's attention having dwelt on this matter, the phenomena have greatly increased in importance; he now hears the bass voice in left ear, the tenor in the right one, whereas at first every sound seemed to enter the left ear.

As regards the aural condition of this patient, I may say that there is no history of any previous disease of the organ. Syphilis is denied. He has chronic catarrhal inflammation of the upper air-tract (hypertrophic). The drumheads are lustreless and somewhat atrophied, the anterior segment of both is dry and wrinkled. The left membrana flaccida is hyperæmic, and has a fleshy appearance. There are other evidences of loss of tension in the transmitting mechanism—thus there is general relaxation of the exterior parts of the ear, the skin in front of the tragus on both sides is notably relaxed, as is shown by several wrinkles. Inflation of the drum with the air-bag has caused the tinnitus to cease for ten or fifteen minutes; closure of the meatus seems to muffle the sounds heard. His own voice never sounds autophonously. Hearing is defective, ordinary voice only being heard distinctly at a distance of ten feet.

I advised the patient to find occupation, and suggested that when not at work he might find relief by keeping in the noise on the streets, etc., as much as possible. He found, however, that the noise of trucks, horse-cars, and other heavy vehicles made him worse, since the loudness of the voices heard was also increased. He found that he was much better after remaining a few days in the country.

Dr. Allan McLane Hamilton, who saw the patient, considers that he has both insane delusions and hallucinations, due to some form of chronic cerebral disease arising from alcoholism, and that he is liable to become a dangerous lunatic. He found the tongue to point slightly to one side, and the pupils to be unequal. It was thought that the ophthalmoscope might throw more light on the case than could be gained from rational symptoms, and Dr. Loring kindly made an examination. Although nothing decisive was found in the fundus, yet he thought the vessels of the left eye had a suspicious look, the veins being very large in some places and considerably tortuous; these conditions might suggest commencing trouble from tumor of the brain or gummata.

Interest attaches to this case, not from disturbance of audition from central causation, but on account of the effect of the *tinnitus aurium* upon a mind already predisposed to insane hallucinations. At first the hallucinations were notably unilateral, seemingly for the reason of greater defectiveness in the left ear. Subsequently, however, his attention was frequently directed to the probable bilateral source of the voices, and then it was that he began to fancy the sounds entered both ears.

I think there can scarcely be a doubt, if I may judge from a very considerable experience among these cases, that sounds in the head of roaring, beating or pulsating, buzzing, whistling, and the like, which are so often propagated from defective ears in subjects of both chronic catarrh and acute aural disease, may give rise to veritable insane delusions in neuropathic subjects. The changes in the transmitting mechanism of the middle ear in these subjects usually give rise to autophonia, and when these phenomena of audition occur in alcoholic or senile persons, the necessary factor in finally producing serious mental trouble may be found.

In this patient the ear disease is well marked; and it would seem that since the drumhead may present recognizable changes in many instances, perhaps in a very considerable number of mentally insane persons, a knowledge of the condition of these parts might be available in forming a diagnosis of the case as well as aiding in the treatment.

SARCOMA OF BRAIN.

DR. KINNICUTT exhibited a sarcoma of the brain, occurring in a boy twelve years of age, with the following history: Four other children of the same parents died

of "water on the brain." Until three weeks before admission to the hospital, February 22, 1886, the patient was reported to have been in excellent health. At this time he began to complain of pains in the calves of his legs. There were no other symptoms until February 17th, when patient complained of not seeing well. For two days before admission there had been occasional vomiting. The patient was able to walk a very considerable distance to hospital. On admission, there was bilateral ptosis; the pupils were widely dilated, and wholly irresponsive to bright light. Complete amblyopia existed. There was no more than a slight uncertainty in the patient's gait. The respirations were regular in rhythm and normal in frequency. The pulse was 78 and regular. Ophthalmoscopic examination showed well-marked atrophy of the optic nerve of the right eye, and slight tortuosity of the vessels. There was commencing swelling of the left optic nerve. There were absolutely no other symptoms than those described above, until twenty-four hours before death, when the respirations suddenly became very rapid and irregular, the pulse very frequent (160); œdema of the lungs supervened, and death ensued. On examination after death a tumor (sarcoma) was found, completely filling the fourth ventricle, encroaching (infiltrating) upon the substance of the cerebellum, and firmly adherent to the pons and medulla. Two small growths of a similar nature were found immediately posterior and adherent to the optic commissure, and also adherent to the optic tract upon either side. The tumor filling the ventricle had not been dissected from its attachments, in order that it might be shown *in situ*.

The case was of interest, as presenting few symptoms until immediately before death, in the presence of a lesion occupying the site indicated above.

Dr. Kinnicutt also read a paper (see page 381) on

THE USE OF THE ŒSOPHAGEAL TUBE IN DILATATION OF THE STOMACH FROM OBSTRUCTION OF THE PYLORUS.

Dr. W. H. Draper asked Dr. Kinnicutt if he had had any experience in the use of the hydrochloric-acid test in the determination of the presence of cancer of the stomach.

Dr. Kinnicutt said that the absence of hydrochloric acid in the gastric juices was exceedingly difficult to determine, and he had been informed that it was a delicate and a misleading process.

The President referred to cases of dilatation of the stomach without obstruction at the pylorus, mentioning especially the fact that, on the second day in one case, while passing the tube, quite a little hemorrhage followed, which probably came from the stomach. This circumstance made him doubt whether the patient was not suffering from ulcer of the stomach; but no recurrence of the hemorrhage took place, and the patient was almost entirely relieved of his indigestion.

Dr. Kinnicutt thought it not very unfrequent to have a slight amount of hemorrhage follow the first and second introduction of the tube, and he had regarded it as coming from the œsophagus rather than from the stomach. It had become his practice to use lavage in all cases of cancer of the stomach, nor did he regard ulcer of the stomach a contra-indication to the use of the tube. Certainly benefit could be gotten from its use, at least as regards temporary relief from distressing symptoms.

Of course, only the soft, flexible rubber tube and the siphon process should be used in these cases, and the tube should never be introduced except by the physician; recent hemorrhages would contra-indicate its use.

The President said that he would be loth to use the tube in a case of ulcer of the stomach.

Dr. Kinnicutt said that no case of perforation of an ulcer by the stomach-tube had been reported. The tube, when introduced, naturally seeks the most dependent portion of the stomach, and this was not the usual site of gastric ulcer. In his experience, retching and vomiting most often occurred with the passage of the tube into the œsophagus; by thoroughly spraying the pharynx with a solution of cocaine, he had found that in many cases this symptom might be avoided.

The President had noticed, however, that the passage of the tube frequently produced a great deal of retching, which he thought not unlikely to bring the ulcer in contact with its extremity.

Dr. A. B. Ball then read a paper (see p. 388) in which he reported a case of

PURPURA HEMORRHAGICA.

Dr. C. L. Dana said the patient whose case Dr. Ball had reported, entered Bellevue Hospital, and was in his wards for two days. During that time he made the diagnosis of purpura rheumatica. On the third day the house physician thought the patient was getting up erysipelas, and he was accordingly sent to the pavilion and put under Dr. Ball's care. Dr. Dana still thought the case was an atypical one of purpura hemorrhagica, and believed that there was certainly some other element in it.

Dr. Ball admitted that the case was not perfectly clear; certainly it presented unusual symptoms, and therefore it was unusually interesting; but he was unable to see what possible connection rheumatism could have with such hemorrhages except through the medium of ulcerative endocarditis, and he had been unable to find any reference at all to such a condition of things occurring in ulcerative endocarditis.

Dr. Dana said that when the patient entered the hospital there was considerable elevation of temperature, which could not be attributed to purpura hemorrhagica.

Dr. Ball thought Dr. Dana was mistaken in saying that purpura hemorrhagica is not a febrile disease; perhaps it is not in most cases, but there are many cases in which it is distinctly febrile.

Dr. Dana said that it might be febrile in the latter part of its course, but not in the earlier manifestations of the disease.

Dr. Draper thought that purpura hemorrhagica should be regarded as dependent on a variety of causes. Hemorrhagic purpura might occur in cases of cirrhotic and fatty liver; it occurs in certain essential fevers; it is not uncommon in cerebro-spinal meningitis; it is seen in a certain number of cases of malignant scarlet fever. The history which Dr. Ball had read seemed to him to be fairly that of a case of so-called rheumatic purpura. He had seen a number of these cases within the past winter. He saw one young lady who gave the history of rheumatism, became very anæmic, and afterward had hemorrhages from the kidneys, and then from the mucous membranes, without very marked but very distinct joint symptoms, who finally died from uncontrollable epistaxis. He had another case, that of a gentleman who for many years had attacks of gout, several of them accompanied by cutaneous hemorrhages, purpuric in character. This patient had cirrhotic and fatty liver, and he ultimately died with extensive purpura hemorrhagica, with connective tissue changes similar to those described by Dr. Ball.

He believed that various diseases brought about the condition of the blood-vessels which gave rise to these symptoms. Dr. Ball's case clearly began as one of rheumatic fever, and terminated, he thought, as one of rheumatic purpura.

Dr. Ball asked what connection there was between the rheumatic fever and the hemorrhages.

Dr. Draper said he did not know. We know that there is no other disease which so rapidly produces extreme anæmia as rheumatic fever, and this anæmia may be so extreme as to bring about such results as exist in the final stages of pernicious anæmia.

Dr. Ball said that Dr. Draper certainly used the term purpura rheumatica in a different sense from that in which it is ordinarily used by writers; for, purpura rheumatica is not a rheumatic affection at all. The joint affection is supposed to have an entirely different explanation.

Dr. Draper said he was aware that different explanations had been given, but he thought that he had seen the disease occur under circumstances when it was impossible to regard the joint lesions other than gouty or rheumatic, because they occurred in gouty and rheumatic persons, and with all the characteristic features.

Dr. E. Darwin Hudson, Jr., remarked as to the question whether rheumatism was a definite disease due to an acid condition, or whether it was a condition of malnutrition of the blood, that it was not easy to see how some cases would develop rheumatism, and others the more advanced changes leading to purpura. He then referred to a case which corresponded to the descriptions given of *peliosis rheumatica;* at the same time it was undoubtedly a well-defined case of subacute rheumatism. It occurred with recurrences at an interval of one year, and also in each instance it was preceded by a well-defined attack of tonsillitis. The patient was an American lady twenty-three years of age, who had an attack of acute tonsillitis about one year ago, for which she was treated by Drs. Gage and Harrison. One tonsil suppurated, and following that she developed the usual symptoms of rheumatic arthritis, with a temperature of 102° to 103° F., for several days, and then there developed the characteristic patches, which at first were red and afterward of a more livid hue, and finally, the cuticle over them became slightly raised, and the whole patch had a leathery, resisting feel. She was treated with acetate of potash and tonics, and recovered, and was entirely well for about one year. In last November she had twenty-four patches of this kind affecting the lower extremities, after having been taken with a chill, general soreness and inflamed fauces, and subsequently developed well-defined symptoms of subacute rheumatism, affecting the wrist, the elbows, knees, and ankles. During the course of this sickness the characteristic spots appeared, varying up to the size of the thumb-nail, perceptibly elevated and resisting. She was treated with salicylic acid and bicarbonate of potassium, and was well in about two weeks. The question arose whether these attacks were septic in each instance, or whether they were rheumatic.

The Society then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 10, 1886.

T. Mitchell Prudden, M.D., Vice-President, in the Chair.

Dr. Prudden presented, in behalf of a candidate, a series of microscopic sections of the spinal cord from locomotor ataxia, which illustrated

WEIGERT'S STAINING FOR THE NERVOUS SYSTEM.

Dr. W. M. Carpenter presented, for Dr. Heineman, in behalf of a candidate, a specimen of

CEREBRAL TUMOR.

It was referred to the Committee on Microscopy. [Subsequent examination showed that it was a small round-celled sarcoma.]

Dr. Eugene Hodenpyl presented specimens, with microscopic sections, with the following history:

FAULTY DEVELOPMENT OF THE PENIS AND TESTICLES.

The patient from whom these specimens were removed was a man twenty-eight years of age. He was of about the usual height and size, and had had phthisis for several years. He died after being in the hospital a few weeks. At the autopsy both lungs presented the lesions of chronic phthisis. There was a large cavity in the apex of the left lung, and several smaller ones scattered about. The other organs were normal. The penis was unusually small, and there was marked phimosis. The right testicle was lobulated, and about the size of a small almond. The epididymis was present, though very small. There was no trace of the left testicle, although a careful search was made for it, both in the scrotum and abdomen. The tunica vaginalis was present on both sides; also the spermatic cords, which were considerably atrophied. The cord on the right side terminated in the rudimentary testicle; the left one, after leaving the internal abdominal ring, gradually grew smaller, and finally became lost. The microscopic sections of both cords showed all the elements of a normal cord. The normal layers in the wall of the vas deferens could be made out in both sections. There was also a section of the testicle which contained a small amount of glandular tissue, composed of tubules lined by cuboidal epithelia, but the greater part of the mass was composed of fibrous tissue.

Dr. Prudden remarked that the specimens were interesting because the atrophied testicle was very apt to remain within the abdominal cavity.

Dr. H. J. Boldt presented

AN OVARIAN CYST,

removed by operation from J. N——, married, forty-one years of age, the mother of two children, the youngest born five years ago. Her menstruation began at the age of sixteen. While single, and until the birth of the first child (eighteen years ago), she suffered from dysmenorrhœa. Had always menstruated regularly, the flow lasting five to six days, except when pregnant or nursing. She had enjoyed good health up to about six months ago, when she noticed a heavy sensation in the pelvis, and some lumbar pains, which gradually increased in severity. When she presented herself to Dr. Boldt, February 3, 1886, she had, in addition to the above, pain in the right inguinal region, radiating down the same thigh; frequent micturition, being compelled to urinate every fifteen to twenty minutes; cardialgia; darting pain in the præcordial region; occasionally nausea; menorrhagia, the flow now lasting ten to fourteen days, and dysmenorrhœa; constipation, and when the bowels did move, it caused much pain and tenesmus. Bimanual examination showed the uterus to be remarkably anteflexed and somewhat to the left of the median line. The cul-de-sac of Douglas was filled with a tense mass, fluctuating slightly, and apparently more on the right side. In size the mass seemed to be about as large as a large orange. The diagnosis rested between a hydrosalpinx and an ovarian cyst, which was low down and not yet large enough to rise out of the pelvis.

Operation was advised, and performed on the following Sunday at her home.

On opening the abdomen the tumor, which proved to be a simple ovarian cyst, was found to occupy a position to the right and behind the uterus. No adhesions had yet formed; consequently its removal was quite easy. The other ovary seeming healthy, was left *in situ*. Recovery was rapid, the patient being out of bed on the ninth day and sitting in an easy-chair, which was more remarkable as the surroundings were anything but good. The temperature kept normal throughout. It is now a little over one month since the operation, and the patient has made a complete recovery, all her distressing symptoms having entirely disappeared.

Dr. Boldt said that the specimen was interesting, especially with reference to the age of the patient, the disturbances of menstruation, particularly the dysmenorrhœa, and as an illustration of the severity of the symptoms which may be produced by so small a growth.

It was one of six successful ovariotomies out of eight cases in patients operated upon in tenement-houses. The case also illustrated the advantage of operating early, before the formation of adhesions.

Dr. Robert Newman presented a portion of the genito-urinary apparatus which illustrated

CYSTITIS WITH HYPERTROPHY OF THE PROSTATE—PYELONEPHRITIS—[illegible]

The patient came under observation in November, 1885. M. T. P——, sixty-seven years of age, com-

plained of pain in the bladder and difficulty of micturition. The urine was cloudy, ropy, and had a fetid odor. He had been ailing for two years in this manner, without asking medical advice. The patient has never been sick, was accustomed to all kinds of hardship, and by predilection slept upon the floor, scarcely being in bed during the last twelve years, although he had about fifty beds in his house. He was obliged to seek medical advice on account of the pain in his bladder and almost impossibility of voiding his urine, and Dr. De La Vergne, of Brooklyn, used the catheter several times; but as it was almost impossible to introduce any instrument, he returned the patient to Dr. Newman for treatment.

December 1st.—Examination: Prostate is much enlarged, encroaching both on bladder and rectum, and so sensitive that digital examination cannot be endured. The pressure makes the prostatic urethral canal tortuous in its course, displacing the urethra. The enlarged prostate fills up the neck of the bladder, being an obstacle to the introduction of a catheter, as well as the flow of urine, thereby causing retention. The bladder is full of finger-thick, ropy masses of phosphates, pus, mucus, blood, and fibrin. Spasm of the bladder caused pain and completed the obstruction. Ordered rectal suppositories of extract of belladonna.

December 3d.—With great difficulty a guide was introduced, over which a tunnelled catheter, No. 9, French scale, passed into the bladder. The instrument was obstructed by pus, blood, and mucus; but by suction and washing out bladder with warm water considerable urine was withdrawn, so that he could void urine again in a small stream, or by dribbling away.

December 8th.—Catheter No. 18 passed with difficulty.

December 12th.—Catheter No. 23 passed easier. Bladder was washed out without causing any hemorrhage.

December 19th.—Catheter No. 23 passed very easily. There is marked improvement. Extract of colocynth is added to the suppositories to relieve constipation, and belladonna given in the medicine to allay pain.

December 23d.—The colocynth added to the suppositories acted well by keeping the bowels normal. Catheter No. 23, French, passed into the bladder easier than ever. Bladder was washed out with a solution of sulphocarbolate of zinc. There is marked improvement, and the patient passed water voluntarily.

January 6, 1886.—The treatment has been interrupted by the sickness and death of patient's wife; thereby patient's condition had become worse. Nevertheless, catheter could be introduced and bladder washed out.

January 8th, 12th, 15th.—On each occasion bladder was washed out by a double canula catheter, No. 23, which passed into the bladder easily, while Mercer's invaginated catheter failed. Patient feels better; voids urine voluntarily, and is improved in every way.

January 16th.—Patient is worse, having neglected himself. During the cold spell he remained in a cold room without a fire, sitting up without being in a bed. He is very feeble, the prostate so congested that no catheter could be introduced.

January 17th.—Dr. Newman visited him in Brooklyn. Patient was weak. After some efforts patient was relieved; took milk-punch, and was left in good spirits at 5 o'clock P.M. At 10 o'clock a sudden collapse took place. Dr. De la Vergne was called, and found patient becoming comatose, evidently suffering from the effects of uræmia. He was sinking fast, and died comatose at 2 o'clock in the morning, January 18th. Autopsy was held on January 19th, thirty hours after death.

The kidneys were found entirely disorganized, of an amyloid appearance; the pelvis was dilated and enlarged to about three times the normal size, and filled with pus. It is evident that the kidneys could not perform their functions, and that uræmia was the cause of death. The ureters were also very much dilated and filled with pus. The bladder was enlarged and thickened, but not to such a degree that the cystitis could have been a cause of death. On the contrary, the mucous lining shows that treatment has improved the condition of the bladder, so that the mucous membrane looks now nearly healthy. The prostate gland is much enlarged, and one part of the third lobe can be seen to obstruct the passage of the urine at the neck of the bladder by tilting over just into the opening of the urethra into the bladder. This state shows plainly why retention occurs, and when these parts are irritable and congested it makes catheterism almost impossible. All the other organs were normal.

Dr. H. Marion Sims presented a small

FIBROID OF THE OVARY

removed from a patient, thirty-four years of age, who had suffered for a number of years with profuse menorrhagia, menstruation occurring regularly and lasting nearly three weeks. It was evident that she had a fibroid of the uterus, and to arrest its growth Dr. Sims determined to remove the ovaries. On opening the abdomen he found a fibroid tumor, about four times the size of the normal uterus, attached to one side of that organ, and, with the ovary on the right side, he removed the small fibroid presented, which was interesting on account of its rarity of situation.

Dr. Sims also presented several specimens of what, for lack of more positive knowledge, he called

ABDOMINAL NEUROMATA,

removed by operation from just beneath the skin of the abdomen of a woman who had always been healthy, was married at the age of seventeen, immediately began to suffer from extreme vaginismus, which was relieved completely by removal of the hymen. Her nervous symptoms disappeared and she remained well for three or four months, when she became pregnant, and in the second month began to complain of severe pain in the region of the left ovary, which increased in severity as pregnancy advanced, and in the sixth month she began to have the most violent hystero-epileptic convulsions, occurring from once or twice a day to one every four or five days. The only relief afforded was from the inhalation of nitrite of amyl. Finally the child was born in July last, but instead of relief coming, the pain increased in severity, and then Dr. Sims found that the left ovary was considerably enlarged and cystic, as was also the right ovary somewhat. With Dr. C. C. Lee in consultation, it was determined to remove the left ovary, which was done, Dr. Lee assisting, and it was found to be about three times the normal size and filled with cysts; the right ovary, being diseased, was also removed. The patient recovered from the operation, the convulsions and pain in the head ceased, and it was thought that all her trouble had been overcome. But about two weeks afterward she began to complain of violent pains in places over the abdomen, about the size of a silver ten-cent piece; getting better in one place and appearing at another; and, finally, there were so many of them that Dr. Sims injected cocaine, and made an incision into the worst one of these painful spots, and removed four little knot-like bodies, about the size of bird-shot and small peas. The patient recovered from this operation, and had no more pain whatever up to about six weeks ago, when she was suddenly attacked with abdominal pain which presented the features of peritonitis, and she was treated for peritonitis. The pain gradually diminished in severity, became more localized, and finally centred in one spot on the right side of the abdomen, where Dr. Sims found another of these little button-like masses, which he incised, and removed a nest of these peculiar shot-like bodies. The pain ceased at once, and the patient recovered from the operation promptly.

The specimens were referred to the Committee on Microscopy.

Dr. Putnam-Jacobi presented specimens which illustrated

PULMONARY CONSOLIDATION — ENLARGED BRONCHIAL GLANDS—PRESSURE UPON ONE OF THE RECURRENT LARYNGEAL NERVES—HEART-CLOT.

They were removed from the body of a German child, three and a half years of age, whom she saw two days before its death, when she learned that it had suffered three months from pertussis, and that during the last six weeks the health of the child had manifestly declined. Three weeks before death, when the child was brought to the dispensary, where Dr. Daniel saw it, the parents said that it could not walk ; but on examination it was evident that the inability to walk was due to general weakness rather than to any definite cause. Two days before death there were extensive bronchial râles, with evidence of pulmonary consolidation. There was present, however, almost complete aphonia. There was an area of distinct dulness on percussion over the upper lobe of the left lung, with absence of vesicular murmur, and with remote bronchial breathing. So far as could be ascertained there had been no fever. On account of the absence of fever she interpreted the physical signs as meaning atelectasis rather than pneumonia. There was no evidence, on percussion, of enlargement of the glands at the root of the lung, although there was a certain amount of lividity about the face that would lead one to suspect pressure upon the right jugular vein. The apparent condition of the lung did not explain the aphonia. No evidence could be obtained to warrant the conclusion that the child had at any time had diphtheria. The child died suddenly.

Autopsy revealed in the upper lobe of the left lung an abscess in the midst of caseous pneumonia, with other patches of ordinary broncho-pneumonia, and in the lower lobe atelectasis. There was nothing of special interest in the right lung. All the glands at the root of the lung were enormously enlarged and cheesy. Where the inferior left recurrent nerve curves around and crosses the aorta, an enlarged gland has pressed upon it, and thus the aphonia was explained. In this respect, therefore, the case was analogous to Parrot's, in which the diagnosis of aneurism at this point was made from the presence of aphonia and unilateral paralysis of the vocal cord.

The probable order of events in the case was engorgement of the glands at the root of the lung, subsequent cheesy degeneration, making the point of departure for the cheesy pneumonia which was present, and which had apparently developed within six weeks. The immediate cause of death was minute coagula, which intertwined about the cardiac valves, particularly marked around the tricuspid. Nothing was found in the larynx.

Dr. Prudden remarked that it was not the rule for caseous material to break down as described.

Dr. R. O. Mason asked if the minute coagula really had anything to do with the death of the patient.

Dr. Putnam-Jacobi thought that the tendency of opinion among pathologists was toward the older view that such clots might be the immediate cause of death.

Dr. John J. Reid presented a specimen of

PERFORATION OF THE CÆCUM FROM PERITYPHLITIC ABSCESS,

with the following history :

A married Bohemian woman, twenty-three years of age, was admitted to the Charity Hospital suffering from pain and swelling in the right gluteal region. She said that four months previously she was delivered of a child, and one week subsequently complained of severe pain in the region of the womb and pelvis, which extended over the sacro-iliac synchondrosis. At this time her legs and ankles swelled, and assumed a glistening, white appearance. This swelling disappeared; but with this disappearance there was an increase of pain in the right iliac region. On admission to hospital, January 6, 1886, there was severe pain in the right iliac fossa, extending outward toward the sacrum. Her left leg was swollen, glistening, white, and solid to the touch. The right side over the gluteal region was swollen, and strongly suggested the presence of pus. None could be obtained, however, by an exploring needle. Poultices were applied, and five days afterward pointing was detected to the right of the promontory of the sacrum. From the opening made at this point a large amount of pus escaped, carrying with it some grape-pits. This settled the question of diagnosis. A drainage tube was inserted, and antiseptic injections used. It was deemed expedient to make an exploratory incision, but the patient persistently declined permission, and there was nothing left but to carry on the ordinary washing-out treatment of the sinuses. Death occurred from exhaustion a month after admission. Autopsy twelve hours after death. Nothing worthy of special note was found, except in the abdominal cavity.

On exposing these organs the viscera were in normal position and of normal appearance, omentum fairly loaded with fat, more than the general bodily appearance would indicate. On searching for the cæcum, etc., the usual peritoneal adhesions were greatly exaggerated, the lower end of ileum, cæcum, and ascending colon firmly bound to posterior wall of abdomen ; the appendix vermiformis short, club-shaped, three-quarter inches in diameter. On removing the intestines and separating the adhesions above described, two perforations of the cæcum, about two inches apart and one-eighth inch in diameter, were found, which openings communicated by sinuses with a large cavity beneath the skin above mentioned, extending from the upper opening, a little to the right of the second lumbar vertebra, upward one inch toward the median line, and from thence downward to the iliac crest, embracing an area shaped like a half-circle, containing a small amount of yellowish fœtid pus. The appendix vermiformis presented no communication with the cæcum, and contained a canteloup or cucumber seed considerably eroded. The cæcum was very much thickened, the mucous membrane containing points of superficial ulceration. The ileo-cæcal opening was reduced by this thickening to half its diameter. The other portions of intestine were normal ; kidneys slightly enlarged, cortices thickened, capsules non-adherent.

One point of special interest was the fact that if an opening had been made at the crest of the ilium near the synchondrosis, the finger could have been carried down to the cæcum, and would have reached the perforation.

Dr. Van Santvoord presented specimens with the following history :

URETHRAL STRICTURE — SYPHILIS — PYELO-NEPHRITIS — SEPTIC ENDOCARDITIS.

M. M——, seventy-three years of age, was admitted to Randall's Island Hospital, December 2, 1885. He was suffering from a deep urethral stricture, through which only a filiform bougie could be introduced. His urine contained one-eighth albumen ; condition otherwise fair. On January 6th, several days after passing a bougie, he had chill, fever, and headache, with pain in the left side of the loins. The next day he had no fever, headache was less, and he felt well. On the third day he had fever, headache, vomiting, tongue dry in centre, urine diminished in quantity, containing one-fifteenth albumen, no casts, and considerable pus. On the fifth day stiffness of the neck, pain in attempting to bend it forward, and a pressure over the nucha, and pain in joints of the left arm, were superadded. A soft systolic murmur was heard over the apex, not transmitted. Subcrepitant râles over both lower lobes, patient somewhat delirious. On the sixth day, pain on moving head or limbs was more marked ; no swelling or redness of joints visible ; direct pressure was noted on the seventh day as causing pain in the left wrist and ankle-joints. On this day twitching

in almost all the muscles of the body, with some rigidity, were noted. A few bluish spots (ecchymoses) observed on chest and abdomen. Fæces and urine were passed involuntarily. The patient passed into coma, and died on the morning of the eighth day after his first chill, which was the sixth of his continuous febrile temperature.

Autopsy.—Several small hemorrhage spots, the size of a pea, in skin. The brain showed four hemorrhages about the size of a ten-cent piece in the pia of the cerebral convexities. On the convexity of the right lobe of the cerebellum was a clot three-fourths of an inch long by one-eighth wide, dipping down one-half inch into one of the sulci. Vessels at base slightly atheromatous. Spinal cord was normal. The lungs were œdematous and congested. The heart was normal in size. The right cavities were normal. The aortic valve showed slight chronic thickening. About one-third of the ventricular surface of the posterior leaflet was coated with an irregular fibrinous mass. The same process involved a small part of the adjacent end of the right leaflet, and ran down on the endocardium for about one-third inch. The endocardium at the edge of the process was infiltrated with blood. The mitral valves showed a patch of grayish recent fibrin, about the size of a small pea, on the auricular surface of each leaflet, affected portions of the leaflets coming in contact when the valve was closed. There was general old thickening of the valve. The aorta showed slight atheroma; size normal. Spleen: Slightly enlarged and soft, capsule extensively thickened, and substance contained two dark infarcts with an area of softening. Kidneys: The left kidney was about one-half larger than normal. Its fat capsule was indurated. The capsule proper stripped easily, showing the body of the organ dotted over with small yellow spots with congested areolæ. The cut surface showed many yellow streaks and dots in the pyramids, and also in the cortex. The same appearance was shown by the right kidney, but not so extensively; it was not so large as its fellow, and contained a cyst the size of a cherry-pit. There was no apparent lesion of the ureters and pelvis. The bladder was contracted; its walls were two-thirds of an inch thick; its mucosa was thrown into ridges, was thickened, and showed great injection and small hemorrhages. At the bulbo-membranous junction of the urethra was a marked narrowing of the canal, which readily admitted an ordinary groove director passed from the bladder. A pocket, one-eighth of an inch in diameter existed in the floor of the urethra, immediately in front of it. The stomach was somewhat dilated. Its mucosa showed a number of small, black, superficial hemorrhages. Several hemorrhages, the largest the size of a twenty-five cent piece, were seen in the mucosa of the colon. The left wrist, shoulder, and ankle-joints were opened, but showed no obvious lesion.

In this case the initial chill occurred several days after the introduction of a filiform bougie into the bladder by a careful house-physician, who takes good care of his instruments. It seems questionable whether this had anything to do with the setting in of the process. The question is raised, if the bougie was the bearer of septic poison, as to how long a time may elapse between septic inoculation by catheterism and the development of symptoms.

A second point of interest was the fact that, although the cystitis and the widely diffused lesions in the kidneys seemed to point to the urinary organs as the point of entrance of the poison, yet the ureters and pelves of the kidneys were apparently normal. This he had seen once before in a somewhat similar case. The third point of interest was the marked resemblance of the case, during the last two or three days of life, to one of cerebro-spinal meningitis, the stiff neck, opisthotonus, pain on moving neck and limbs, and delirium being very deceptive. As the cord and the joints showed no lesion, the pain, etc., seemed to be only the arthralgias due to septic poisoning. The heart lesion could not be connected with the systolic apex murmur heard during life.

Dr. Prudden said that if the specimen had been in alcohol the question of presence of endocarditis could be settled by examining the exudate for bacilli. He had seen six or seven cases where general infection occurred, and the ureters and kidneys were skipped entirely. It was sometimes difficult in these cases to discover the source of infection because of the great extent of surface affected.

Dr. Prudden then presented a specimen of

CARCINOMA OF THE CERVIX UTERI INVADING THE BLADDER, OCCLUDING THE OPENINGS OF BOTH URETERS, AND CAUSING HYDRONEPHROSIS AND PYONEPHROSIS.

He was indebted for the specimen and clinical history to Dr. E. R. Lyon, resident physician to Charity Hospital. The patient was a German female, seventy years of age. On admission she complained only of a little cough, and was very feeble; she was stupid, and at times mildly delirious. She was not much emaciated, but had a sallow, cachectic appearance; no fetid discharge was noticed from the vagina. She gave the physical signs of bronchitis. There was considerable œdema of lower extremities. The pale alkaline urine had a specific gravity of 1.010, and contained two and one-half per cent. of albumen. It contained pus in considerable quantity. She remained in the same stupid condition, and died suddenly four days after admission. Autopsy: Heart, normal; lungs, bronchitic. The pelvis and ureter of the left kidney were filled with pus. The kidney substance was somewhat encroached upon by the accumulation of pus in the pelvis.

The right kidney was converted into a thin-walled sac, 12 ctm. long, 9 ctm. wide, and 5.5 ctm. thick, with internal partitions representing the original calyxes. There was a thin layer of kidney substance lining the sac. The right ureter was completely occluded as it entered the bladder, and was dilated to a diameter varying from seven millimetres to two centimetres. The pelvis and ureters together contained 300 c.c. clear amber urine, sp. gr. 1.010, containing no albumen, but considerable numbers of hyaline casts, fatty epithelial cells, and ordinary urinary and cholesterin crystals.

The cervix uteri was completely ulcerated away. The body of the uterus was small, and infiltrated with white, soft, irregular masses of new tissue. The left ovary was small, and not involved in the new growth. The right ovary was concealed in a nodular mass of hard new tissue, which attached the uterus to the bladder.

At the base of the bladder, over the seat of the new growth, was an ulcer 2 ctm. long by 1½ ctm. wide, with slightly raised edges and a grayish smooth surface.

It was the new tissue at the base of the ulcer which had caused the complete occlusion of the right ureter and the partial occlusion of the left.

Microscopical examination of the new growth showed it to be *carcinoma*.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, March 8, 1886.

STEPHEN SMITH, M.D., CHAIRMAN.

Dr. W. B. De Garmo read a paper (see p. 386) entitled

THE PALLIATIVE OR MECHANICAL TREATMENT OF HERNIA, WITH ILLUSTRATIVE CASES.

Dr. V. P. Gibney said he had been a trifle disappointed that the author of the paper had not gone into the subject of the radical cure of hernia by mechanical appliances, because he had been looking for radical cures by means of the truss, and yet, in common with the bulk of the profession, he had doubted the existence of very many radical cures by any kind of truss. It was well known that certain truss-makers in this city advocated the radical cure, and it was also believed by medical gentlemen that

such cases did occur, and, as evidence on this point, he could cite one case he saw in 1884, with a distinct inguinal hernia, and to which he adjusted a truss that held it for a while and then failed to accomplish its purpose. He then took the patient to a truss-maker, who made an instrument and applied it, and the patient wore it for two or three months, when it also failed to afford relief. The patient then disappeared from his observation, and he saw nothing more of him from 1884 until a few days ago, when he met him and was told that he went to a down-town man two or three times a week, for three months, in the summer of 1885, had a truss adjusted that cured his hernia so that he had not been obliged to wear a truss in three or four months. Dr. Gibney said that the patient was a very active man, and that he also regarded him as truthful in his statements, although he had not had opportunity to examine the case personally.

The cure by injections was on the same principle that the Germans had employed other substances, such as alcohol once or twice a week for several weeks, and had reported good results.

With regard to reducible herniæ, he had seen a large number of cases in which taxis was not dangerous, and he believed that intelligent taxis could be employed with safety and good results. He did not, therefore, advocate as early operation as some of his surgical friends.

His firm belief was that fully ninety per cent. of the cases of hernia occurring in infants could be cured within twelve months by wearing any truss with a pad which fits sufficiently well to retain the hernia. His inflexible rule was to reduce the hernia, adjust a truss which could not be taken off by the parents, and aim to so retain the hernia that it should never be seen after its first reduction. During the first month he saw his patient once in two or three days; after that at much longer intervals.

Dr. F. D. Weisse said that hernia, both from an anatomical and a surgical standpoint, had been with him a favorite subject of study. It was certainly the opprobrium of surgery that so many cases of hernia went unrelieved, and had been turned over to the treatment offered by those who had no special knowledge of the condition of the parts involved.

His own view was that not sufficient consideration had been given to the causes of hernia, and that the area of support should extend over the entire hypogastric and opposite inguinal regions. Dr. Weisse then spoke of the anatomy of the inferior third of the abdominal parietes, and he thought that anatomical considerations would support the deduction that this whole area contributed to the cause, increase, and perpetuation of hernia.

The tip of the index-finger, when adjusted against the protruding contents, was sufficient to give perfect support, and this was the principle involved in the various forms of pads. But in addition to this, he believed that the lower part of the abdominal parietes should be thoroughly supported. To secure this he referred to the application of a plaster-of-Paris cast to the lower third of the abdomen while the patient was in the recumbent posture, being careful at the same time to know the exact point at which the pad of the truss should be applied.

He also thought that too little was taught with reference to taxis, and too much said against it. Unfortunately, in very many instances it was improperly applied, but when intelligently employed he thought it was a very great adjunct in the management of herniæ.

With regard to hernia with undescended testicle, he had seen several cases in which a useless testicle was the result of the application and the wearing of a truss.

It was a new point to him that a truss could be worn without danger when the hernial tumor was composed of omentum, and he regarded it as a point well worthy of special study. Dr. Weisse then referred to the value of percussion in determining the character of the contents of the hernial tumor. He would also ask Dr. De Garmo if there was a definite time at which he regarded it safe to leave off the truss.

Dr. John C. Peters said that, up to the present discussion, he had been of the opinion that the entire subject of hernia had retrograded since forty or fifty years ago, at which time Amos G. Hull, Sr., was the man in this city who paid most attention to this subject. He was the first to use the long arm of a spring in front from the side opposite to the hernia; who used a broad sacral pad, and was especially careful to mould his springs to the shape of the body; who insisted that the truss should never be removed until the patient was lying down, and that the patient should never get up until after the truss had been adjusted; who used a convex pad surrounded by a ring; who employed an abdominal support; who applied a truss for a descended omentum; and who used a truss with success in the treatment of varicocele. The exact form and mode of adjusting the truss in these cases he had been unable to ascertain.

Dr. F. A. Burrall said that he had been led by his experience in the direction of the remarks made by Dr. Weisse, that there had been a lack of adaptation in the use of mechanical appliances. He believed that the abdominal bandage should be applied more often than it had been, for it divided the support and it was a very great addition to the comfort of the patient. He regarded prophylaxis as an important factor, especially in the way of timely support of the abdominal parietes after exhausting illness.

Dr. A. Jacobi had always been under the impression that no bandage or truss would ever cure hernia in the adult. On the other hand, he fully agreed with what Dr. Gibney had said concerning hernia in children. When an infant wears a truss for one or two years in succession, and protrusion of the intestine does not take place during that time, he regarded it as a certainty that the hernia had been cured. To accomplish this a truss is required which retains the hernia and exercises gentle pressure on the soft parts. It had not been his practice to keep the truss on during the night, except when the child had a cough.

Dr. Stephen Smith stated that it had not been his fortune to see many cases of cure of the herniæ of adults, either by means of the truss or operative procedures. He used the term cure in the sense that the profession generally understand it, viz., such a cure that the patient can with impunity dispense with the truss altogether. The reason for this failure seemed to him to be due to the fact that a hernia in an adult indicates a loss of integrity in the lower abdominal walls, which cannot be compensated by any changes which a truss or an operation can secure. All he ever contemplated accomplishing with a truss in an adult was the easy, but constant, retention of the bowel within the abdominal cavity. This is a great gain to the patient, for, as the enlargement of a hernia depends upon a gradual lengthening of the mesentery, the natural support of the bowels, the more effectually the bowels are retained within the abdomen, the less is the disposition of those organs to descend, owing to the tension of the mesentery. As to the various operations for the radical cure of hernia, he had performed many of them, and had yet to see any such results as would warrant the removal of the truss at a given date with the certainty that the hernia would not return. He had seen them well after six months, but the larger number returned within a twelvemonth after the patient dispensed with the truss. In practice, he had come to believe that when a hernia appears in an adult, a properly adjusted truss was to be worn the rest of the patient's life, whether an operation was performed or not. There is no doubt that the operations are useful, but in his own practice, whatever operation was performed, he insisted upon the patient's wearing a light-fitting truss continuously after the cure was apparently completed. He recalled a conversation with Dr. James R. Wood, who frequently operated, in which Dr. Wood stated that he regarded the continuous use of the truss as an essential part of the after-treatment in all operations. He also

recalled a statement of Mr. Banks, of Liverpool, who has had a large experience in operations upon herniæ, to the effect that the term "radical cure" is misleading. The popular belief, in the opinion of this surgeon, that a patient upon whom a radical cure has been performed need never again wear a truss, nor ever again be in danger of his hernia coming down, was, in his experience, far from being true, and the instances where a light truss can be dispensed with are in the minority. He says very pertinently that to determine results we should see the patient one year after he left oft his truss, and learn what he has been doing meantime. Dr. Smith regarded the truss as the great palliative measure on which reliance must be placed after a hernia once appears in an adult, and hence the necessity of the greatest care in the selection of these instruments. One kind of truss cannot be adapted to all cases, and great skill and experience are necessary in the selection for each individual patient.

Dr. De Garmo said he had not spoken of the radical cure of hernia because it was his purpose to consider that in another paper, and he had restricted himself, therefore, to the palliative cure of hernia. As this point had been brought up, however, he would say that he thought skilled mechanical appliances would cure as large a percentage of herniæ as any operation performed in these days. It was this fact which enabled quacks to obtain their certificates.

With regard to hernia in infants, he regarded cure as certain when proper treatment was instituted, by means of mechanical appliances, any time prior to ten years of age, and he did not regard the recumbent posture as essential to effecting this cure. Doubtless it aided, but it was not necessary. He thought it just as well to delay the treatment of hernia in children by mechanical appliances until the child was three, four, or five years old.

With regard to supporting the lower part of the abdominal parietes, it seemed to be well in theory, but he had not found it so valuable in practice, for there were cases in which such support seemed to press the contents of the abdomen downward and interfere with retaining the hernia by means of a truss.

With regard to the use of a plaster-of-Paris cast, he noticed this method when it was first published, but he was unable to see how it could be made available in the treatment of hernia.

With regard to the removal of the truss, he judged entirely by the condition of the parts; there could be no prescribed limit of time with reference to its removal. He thought that Dr. Peters was in error in ascribing the cross-body spring to Hull, because Sir Astley Cooper had mentioned this spring as the invention of Solomon Ody, in 1803.

With reference to the treatment of varicocele, Curling had recommended a truss for the radical cure of varicocele arranged so as to make direct pressure over the external abdominal ring. He continued the use of the truss during the night in the treatment of hernia in children, because they were so liable to have the hernia protrude as the result of crying or change of position, etc.

Dr. Jacobi referred to the use of pads filled with air, as he had recently seen one which seemed to work very well, and he would ask Dr. De Garmo if he had had any experience in the use of this form of pad.

Dr. De Garmo said that the air-pad was not being used very much now, but the water-pad was used somewhat. Both, however, had been almost entirely discarded.

Dr. W. M. Carpenter said that, from the remarks made by the author of the paper, and also by Dr. Weisse, it might be inferred that direct inguinal hernia did not exist. If correct in this inference, he would like to place upon record a case which came under his observation several years ago. A man about sixty years of age had had a knuckle, perhaps the size of a walnut, in the right groin for several years, but it gave him no inconvenience up to the time when he lifted a large basket of potatoes into his wagon. He then felt that he had strained himself in this region, and immediately began to suffer from pain referable to this small knuckle, which he at once discovered was slightly increased in size. His family physician saw him a few hours afterward, and reached the conclusion that the swelling was a hernia which had become strangulated. He endeavored to reduce it by taxis, but failed. He then called consultation, and taxis was again resorted to, but failed. Every effort at taxis increased rather than diminished the size of the tumor; the taxis was made as for indirect inguinal hernia. At the end of three days it was decided that relief could not be afforded the patient, except by surgical interference, and Dr. Carpenter was asked to perform the operation He found a small sausage-shaped tumor in the right inguinal region, and, after the usual incisions had been made, he discovered that the opening through which the mass of omentum (omentocele) protruded was the external abdominal ring. The constriction was readily relieved, and the contents of the hernia, in a viable condition, were returned to the abdominal cavity.

The patient recovered from the influence of the ether, conversed intelligently, but, as a precautionary measure against the occurrence of an inflammatory process, a dose of opium, equivalent to twenty drops of laudanum, was administered. About six hours afterward the patient began to manifest some symptoms of stupidity, afterward became unconscious, and died comatose at the end of about twenty-four hours.

Post-mortem examination did not reveal any apparent cause of death. All the organs were apparently healthy. The hernia had been completely reduced, it could be distinctly seen that it had protruded from the external ring, and there was no evidence whatever of inflammation. The wound had united almost entirely.

Dr. Weisse said he did not wish to be understood as saying that direct inguinal hernia did not occur; but he thought it exceedingly rare, and he had never seen a case.

Dr. De Garmo thought it possible that a good many cases of so-called direct inguinal hernia were ventral in character.

Dr. John C. Peters offered resolutions with reference to the death of Alfred C. Post, M.D., LL.D., which were seconded by the Chairman, and unanimously adopted.

The Section then adjourned.

ON CERTAIN PROBLEMS IN THE PHYSIOLOGY OF THE BLOOD-CORPUSCLES.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE ASSOCIATION OF THE ALUMNI OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, MARCH 23, 1886.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF [illegible] IN THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

LECTURE II.

DEGENERATION AND REGENERATION OF THE CORPUSCLES.

THE conception of the blood as a fluid tissue, the corpuscles representing the cells and the plasma the matrix, is not a very happy one, as both cell elements and matrix present peculiarities unknown in any other tissue. Rather is it to be regarded as an internal medium, to use Bernard's phrase, bearing the same relation to the constituent tissues as the external medium does to the individual.

In spite of local variations, the composition and characters of the blood present a remarkable uniformity, the result of the combined action of the receptive, excretory, and formative tissues, which are concerned in the digestion and absorption of food, in the discharge of waste, and in the renewal of worn-out elements.

The maintenance of the histological uniformity of the blood is absolutely dependent upon the integrity of these processes. In health the waste and repair of the corpuscles are not accompanied by any striking or obvious phenomena. The corpuscles present a remarkable sameness, and we cannot pick out with readiness the old elements ready to die, or the new ones which have just made their appearance. This it is which makes the blood such a puzzle, for the corpuscles, so far as observation goes, neither die nor are born in the circulating fluid, but appear to enter it as perfect elements, and are removed from it before they are so changed as to be no longer recognizable.

That the red corpuscles in health are constantly degenerating and as constantly being reproduced, is universally acknowledged, though the facts upon which this belief is based are not very numerous. There is evidence that the coloring matters of the bile and of urine are derived from the hæmoglobin, and to supply their daily amount many corpuscles must be destroyed, and to replace which new ones must be formed. The variations in number at different times and under different conditions indicate that waste and repair are ceaseless processes. Moreover, there is the direct evidence in the presence of degenerating red corpuscles in certain organs, spleen and bone marrow. Our very imperfect knowledge of the details of degeneration and regeneration of the corpuscles in health has been supplemented to some extent by experiment and by the study of the blood in disease, and I propose in this lecture to touch upon the salient features of these processes so far as we at present understand them. As it is difficult to separate the two conditions, which in many instances coexist, I shall first take up the consideration of the state of the corpuscles in anæmia, as induced either by increased destruction or loss of the corpuscles, or as it results from scanty production. The loss may be sudden, as from hemorrhage or acute poisons, or be a slow, gradual process, as in fever and chronic poisoning. Anæmia from imperfect production of cells may result from primary changes in the cytogenic tissues, or be a secondary effect of imperfect nutrition; but in either case the reduction in the number of the red corpuscles is by far the most important change, and upon this the symptoms mainly depend.

In health the red corpuscles present a remarkable uniformity in size, or perhaps it is more correct to say that the variations which occur are within very narrow limits. The large proportion of the corpuscles have a diameter of 7.5 μ, but there are a few to be found which measure a micromillimetre less or more, 6.5 or 8.5 μ. These slightly smaller and slightly larger forms are not numerous in normal blood, not so numerous, I think, as Hayem's[1] researches would indicate, for he places the medium-sized at seventy-five per cent., the smaller forms at twelve per cent., and the larger at twelve per cent. Gram,[2] who has made a number of careful observations on this point, finds the average diameter to be a little more than 7.5 μ (7.8 μ), but the percentage of corpuscles of less or greater diameter varies greatly in different individuals. In the new-born, and for some time after birth, the maximum and minimum diameter of the red corpuscle presents a much wider range, the variations being from 10.3 μ to 3.3 μ. One of the most striking alterations of the red corpuscles in certain diseased states is a reversion to this embryonic or infantile condition, with a variation in the size of individual corpuscles to a degree which is truly remarkable. Instead of an extreme variation of 2 μ as in health, the range between the smallest and largest forms may be from 8 μ to 10 μ, or even more. Thus, minute corpuscles may be measured from 2.5 μ to 3.5 μ, while contiguous cells may be as much as 10, 12, or even 14 μ. To these abnormal forms the terms microcytes and megalocytes have been appropriately given.

Mycrocytes occur normally in the blood of the embryo (Fig. 10, *b*) and new-born, but are rarely to be seen in a healthy adult. In disease they are most abundant in

FIG. 1.—Outlines of Red Corpuscles in [illegible] Normal corpuscles. [illegible] forms—poikilocytes, [illegible]

anæmia, whether from hemorrhage or as a result of changes in the cytogenic organs, or secondary to disease of important viscera. When the attention of observers was first directed to these bodies it was thought that they might be of diagnostic import in certain forms of anæmia, but we know now that they occur—in variable numbers, it is true—in all forms, in chlorosis, splenic anæmia, pernicious anæmia, leucæmia, Hodgkin's disease, and in the anæmia of

[1] Leçons sur les M[illegible]

[2] Deutsch. Archiv f. M[illegible]

cancer, phthisis, and other chronic affections. I must say, however, that so far as my personal experience goes I have not met with them so uniformly or so abundantly in any condition as in those cases which we designate by Biermer's name of progressive pernicious anæmia. In what may be called the primary anæmias they are almost invariably to be found, while in the secondary form they are variable and may be absent. There is unfortunately a difference of opinion as to the nature and origin of the microcytes, some regarding them as disintegrated remnants of corpuscles, others as young forms in process of development. Possibly both views may be correct. The small, spherical bodies of a deep red color, 1.5 to 2.5 μ in diameter, should, perhaps, be distinguished from the forms slightly larger, more distinctly discoid, and less deeply tinted. That they may result from changes in the ordinary red corpuscles is, I think, certain. I have frequently noticed that they appeared to increase in a slide kept for observation. They resemble, too, particularly the small, deep-red ones, the fragments into which the red cells disintegrate under the influence of the induction stream and of various solutions. In a freshly prepared slide of anæmic blood, firm pressure on the top cover will sometimes be sufficient to produce a large number of microcytes which result from the destruction of the red corpuscles by pressure. They may, indeed, be observed in process of formation as shown at Figs. 2 and 3. Normal blood in Pacini's fluid does not often show

Fig. 2.—Extreme Poikilocytosis in Blood from Anæmic Patient, examined in Pacini's Fluid. It illustrates also a possible mode of origin of the microcytes.

special changes in the form of the corpuscles, but the corpuscles, in cases of profound anæmia, may become in it very irregular in outline and deeply fissured, as sketched at Fig. 2, and portions may separate and appear in the field as microcytes. In the bone-marrow, too, I have often noted a somewhat similar process (Fig. 3),

Fig. 3.—Origin of Microcytes from Normal Corpuscles by Process of Budding and Fission. Specimen from red marrow.

and by a sort of budding and fission many small forms may arise. These microcytes are not always to be regarded as a result of post-mortem change—they may be seen in blood examined with the greatest possible rapidity after removal. Whether the slightly larger form of microcytes, from 2.5 to 5 μ, and which are often less deeply tinted, arise in the same way, is still an unsettled question. They occur with the others, but are regarded, as I shall point out later, by many good observers as developing forms.

The *megalocytes* have attracted less attention than the smaller forms, but are equally curious. The term may be applied to forms above 8.5 μ or 9 μ in diameter. They may reach an extraordinary size, 12, 14, and even 15 μ. They are very constant elements in cases of pernicious anæmia, and also occur in chlorosis and leukæmia. Gram[1] has made the interesting observation, which I have been able to confirm, that these forms occur in numbers of cases of icterus. He also states that ordinary red corpuscles placed in icteric serum (of ascites in cirrhosis) seem to increase somewhat in size. We may call to mind in this connection the peculiar lemon or subicteroid tint of the skin in many cases of pernicious anæmia, and possibly there may exist in the blood-serum some element—the product of destruction in the hæmoglobin—which may act upon the red cells and cause them to assume a more flattened form. These megalocytes often show the most eccentric changes in outline, to which I shall shortly refer. When I speak of the development of the corpuscles, I shall return again to these forms.

In the normal red corpuscles regularity in outline is not less constant than uniformity in size, but in the blood of the various anæmias we now recognize the loss of this character as a very distinctive feature. Here, also, many of us erred in supposing this condition to be peculiar to pernicious anæmia, the disease in which these irregular forms were first accurately described. Quincke called them *poikilocytes*, a term which has been very generally adopted. At Figs. 1 and 2 this condition is represented. The corpuscles may present the most remarkable shapes, ovoid, elongated, pyramidal, balloon-shaped, with indented edges, or rods straight or bent at right angles. Many of these bizarre forms are scarcely recognizable at first as red corpuscles. I still hold that we meet with these forms in a more extreme degree in cases of a pernicious anæmia than in any other disease, but they occur also in the anæmia of phthisis, cancer, and inanition. This is a physical change depending probably upon alterations in the blood-serum. It is not induced in the healthy corpuscles by dilution of the serum or slight grades of concentration, or by any of the reagents which tend to produce crenation. In Pacini's fluid the corpuscles of anæmic blood may sometimes be observed to become much more irregular in form (Fig. 2).

Percentage of hæmoglobin.—We know as yet little or nothing of the processes associated with the production of the coloring matter of the corpuscles. In a state of health the percentage of hæmoglobin in each cell is tolerably definite, varying within very slight limits. In diseased conditions we have learned to recognize two remarkable changes in the relation of the coloring matter of the corpuscles. One is the observation made some years ago by Duncan (1867) that the hæmoglobin in chlorosis was reduced out of proportion to the reduction of the corpuscles, so that the individual worth of each red corpuscle in coloring matter might be very greatly lowered. The true anæmia might be much greater than the number of red corpuscles per cubic millimetre might indicate. Subsequent researches have fully borne out this fact, for which, however, we have as yet no suitable explanation. The pallor of the corpusles may even be recognized with the microscope. In ordinary anæmia from hemorrhage or organic disease, the average worth in hæmoglobin of each corpuscle usually remains unaltered, and the percentage of coloring matter corresponds closely with the percentage of the corpuscles; but in certain cases of pernicious anæmia the interesting fact has been ascertained that the percentage of hæmoglobin in each corpuscle is increased, and the anæmia in reality may not be so great as the reduction in the number of red corpuscles would appear to indicate. The individual worth of each corpuscle in hæmoglobin may be actually doubled, and the heightened color be evident on microscopic examination. These two facts, intensely interesting and suggestive, may be said to comprise our knowledge of the changes in hæmoglobin percentage in the corpuscles in disease, and they serve as a background against which to display our ignorance of this most essential feature in hæmatogenesis.

Nucleated red corpuscles.—In anæmic states there may be present in blood nucleated red corpuscles such as normally occur in the blood of the embryo, and such as are present in the red marrow of the bones. I have not met with these elements so frequently as the statements of certain observers (Ehrlich) would lead us to suppose. Certainly they do not occur in all cases of

[1] Archiv für Heilkunde, 1885.

profound anæmia. I have met with them in leucæmia in larger numbers than in any other state (Fig. 4). They present characters identical with the nucleated red cells, which I shall speak of shortly in connection with the regeneration of the corpuscles. They are usually a little larger than the ordinary red corpuscles, and the tint may be slightly paler. The nucleus may be seen in process of division, and I have seen corpuscles

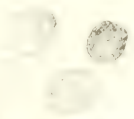

Fig. 4.—Nucleated Red Blood-corpuscles from Blood in case of Leucæmia.

in process of fission identical in appearance with those long ago described and figured by Kölliker as occurring in the blood of the embryo. They may not infrequently be found in groups of three or four, close together, or even in contact, as if the group had resulted from the division of a single corpuscle. I was particularly struck with this feature in one case of leucæmia in which they were very abundant, and I regard the explanation just given as a very likely one in the light of the recent observations of Bizzozero upon the rapidity of the process of division in these red forms. That they originate in the bone-marrow there can be no doubt, and in my experience it is just in those conditions in which this tissue is hyperplastic that they occur in the blood.

A rare and odd element in the blood is the *corpuscle containing red blood-corpuscles*. Several observers have noticed the presence of red cells inside colorless corpuscles in the circulating blood. It is very uncommon, and the sketches at Fig. 5 represent the only examples which I have met with. Considering the abundance of these cells in the marrow, spleen, and lymph-glands in certain states, it is surprising that we do not find them more often in the blood. It is quite possible, however, that the colorless corpuscle circulating in the blood may itself take up a red cell into its interior, just as it may an oil-drop or a particle of pigment. I have a sketch of a colorless corpuscle of the

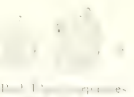

Fig. 5.—Corpuscles containing Red Blood-corpuscles from blood of child with leuæmia. 2. Connective-tissue corpuscle containing pigment.

blood of the frog, with three or four human red corpuscles in its interior which it had *eaten*. I have sought in vain, in chronic malaria, for evidence that the leucocytes in the blood take the corpuscles entire into their interior in the formation of the black pigment. They would appear to take in the disintegrated particles, possibly in the spleen and liver, but not the entire cells.

It is interesting to compare the sketch I have thus given of the state of the corpuscles in anæmia with the condition of the blood in the acute anæmia following a profuse hemorrhage, either accidental or experimentally induced. With our present knowledge, there is a really serious difficulty in deciding just what features of the blood indicate degeneration and what a process of regeneration. Thus, the microcytes, as I have stated, are regarded by some as evidence of a retrograde process, by others as indicating repair of the waste. In an animal deprived of one-third of the amount of blood, or in an individual after a severe prostrating hemorrhage, the changes noted are almost identical with those already described. 1st. The red corpuscles display irregularly in size and shape. The microcytes are numerous and resemble in all respects those of chronic anæmia. The larger forms of red corpuscles are not so constant. Poikilocytes also occur. As the percentage of red cells approaches the normal, these irregularities diminish in a marked manner. 2d. The colorless corpuscles are relatively, and may be even absolutely, increased in number. This doubtless is the result, in part, of a relatively smaller loss in white corpuscles in consequence of their adhesive, wall-loving property, and in part to the flooding of the blood-current with leucocytes poured in with the copious flow of lymph which takes place to make up the volume of blood. 3d. The nucleated red corpuscles may appear. In the experimentally induced anæmia in animals (dogs) they are more abundant than after profuse hemorrhage in man (cirrhosis, hæmoptysis). 4th. There is a marked increase in the number of the blood-plaques.

Regeneration of the corpuscles.—There is probably no subject in physiology upon which opinions differ more widely than in the mode of formation of the corpuscles—particularly the red—after birth. The possibility of a solution of the question seems to have been offered in the discovery of the blood-forming function of the red marrow by Neumann and Bizzozero, and the positive assertions of Hayem regarding the blood-plaque

Fig. 6.—[illegible] corpuscle. *c*. Connective-tissue corpuscle from subcutaneous tissue. [illegible] intracellular development of red blood-corpuscles.

and its connection with regeneration have served to arouse again the interest in this important question.

I propose to lay before you briefly a statement of the current views, as interpreted in the light of more recent investigations, and I shall first direct your attention to the study of the formation of red corpuscles in the *bone-marrow*.

I begin with this, as I here feel more at home, having for some years been an observer of this tissue in various states, and having arrived at certain conclusions which

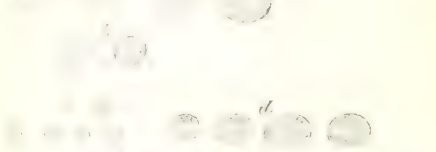

Fig. 7.—Cells from the Marrow of [illegible]. *a*. Smaller, more [illegible] cells. *c*. Free nuclei, or small lymphoid cells, some of which may [illegible] provided with a delicate rim of protoplasm. *d*. Corpuscle with clear, translucent protoplasm.

appear to me justifiable. The red marrow, which in the new-born and young child occupies the bone-cavities of the entire body, is confined in the adult to the cancellæ of the short and flat bones, but even with this limitation the entire bulk is very great, and if massed as one organ would exceed considerably the volume of the spleen. Without entering into preliminary histological details on the structure of the marrow, which are now incorporated in the text-books, I shall proceed at once to the consideration of the cell-elements of this tissue. With a fine capillary pipette, a small quantity of the soft red marrow is placed upon a slide without

any reagent and a thin cover applied with gentle pressure so as to procure a layer of uniform thinness. The plasma of the marrow is usually quite sufficient, and there is serious objection to the addition of any reagent, as the delicate-colored stroma of many of the cells may be at once altered. I feel sure that neglect of this precaution, so strongly emphasized by Neumann, has time and again prevented observers from seeing the very objects they were in search of, and they have ended with a denial of their existence (Rutherford, "Histology"). Examined in this manner we can usually see the following elements: 1. Ordinary marrow-cells (*a*), with coarsely granular protoplasm (Fig. 7, *a*), coarser-looking than that of a colorless blood-corpuscle. The nuclei may not be apparent at first, but they gradually become distinct, two or three in number, oval, round, or reniform in shape and vesicular in character. On the warm stage these elements display feeble amœboid movements.

b. Smaller cells about the size of colorless corpuscles, with more solid nuclei and less granular body protoplasm; they are not so numerous as the larger cells and some of them may be colorless blood-corpuscles.

2. Marrow-cells (9 to 12 μ in diameter) with smooth homogeneous protoplasms (Fig. 7, *d*) and finely granular nuclei, indistinct on first examination, but becoming more apparent in a few minutes. The protoplasm surrounding the nucleus is translucent, homogeneous, colorless, and variable in amount. There may be a single large nucleus surrounded by a narrow rim, or there may be a dumbbell-shaped nucleus, or it may be divided into two or even three. The process of indirect division of the nucleus can be well traced in these forms. Certain of the cells may present the faintest possible tint of color, and as they are carried about among the other corpuscles they show a peculiar flexibility.

3. Small lymphoid elements, resembling free nuclei; solid-looking, homogeneous, 2.5 to 5 μ in diameter (Fig. 7, *c*). They resemble the smallest lymph-corpuscles, but about many of them no distinct rim of protoplasm can be seen. In others there is a faint border of protoplasm. These bodies are variable in number, but they may be regarded as constant elements of the red marrow. Identical structures may be found in the spleen (Fig. 11, 4). They are well described by Norris as the "primary lymph-cell."

4. Nucleated red corpuscles, which we may regard as the special element of the red marrow, and which are present at all periods of life, Fig. 8, *a*. They range in size

FIG. 8.—Nucleated Red Cells of Marrow. Illustrating mode of development into the ordinary non-nucleated red corpuscle. *a*, Common forms of the colored nucleated cells of red marrow. *b*, 1, 2, 3, gradual disappearance of the nucleus. *c*, large non-nucleated red corpuscle resembling 2 and 3 of *b* in all respects save in the absence of any trace of nucleus.

from 6 μ to 12 μ, and are circular or slightly ovoid in shape. When freshly examined the protoplasm is homogeneous, clear, and the nucleus indistinct. The color

FIG. 9.—Nucleated Red Corpuscles. Illustrating the migration of the nucleus from the cell, a process not infrequently seen in the red marrow.

is of all grades up to the intensity of an ordinary red corpuscle. As they float about in the current they show the flexibility and elasticity of the ordinary colored forms. The nucleus may be simple and large, and is frequently seen in all stages of division. It is not colored. In certain cells there are appearances which indicate that the nucleus undergoes changes prior to disappearing, becoming granular and indistinct. In some specimens the nucleus can be seen adherent to the edge of the cell, as if in process of migration from it (Fig. 9), and bodies of a similar appearance may be seen in the immediate vicinity of the red cells.

5. Red corpuscles of ordinary form and appearance. Upon their abundance or paucity depends the color of the marrow. In addition to the usual biconcave disks there are commonly megalocytes, especially if the marrow is hyperplastic, and a variable number of microcytes. The larger corpuscles are, I think, more frequent than the smaller ones.

6. Myeloplaques or giant-cells, the description of which need not detain us, and

7. Corpuscles containing red blood-cells (Fig. 6, *b*, 1). Some of these are evidently collections of red corpuscles undergoing disintegration to form the cells containing granular pigment (Fig. 6, *b*, 2), while others, resembling rather the giant-cells (Fig. 6, *b*, 3) may possibly bear a different interpretation.

The chief interest centres in the nucleated red corpuscle of the marrow and of the spleen. From what does it originate? What is the process of its conversion into the ordinary red disk? All are agreed as to its importance in blood-making. It is the earliest red corpuscle in the embryo; it is constant in the cytogenetic tissues of all animals, and it would be unreasonable in the highest degree to suppose that in the red marrow of the adult it was present for any other purpose. Moreover, in states of anæmia and after bleeding, the nucleated red corpuscles increase in the bone marrow, and even appear (overflow) in the blood; and lastly, Bizzozero has watched the process of division, which may occur with remarkable rapidity, within fifteen minutes. My observations lead me to regard the nucleated red corpuscle as the product of transformation of the clear-bordered homogeneous marrow cell, as all grades of tint can be seen, between cells with scarcely a trace and strongly colored forms. There is no essential difference apparent in the body protoplasm; in both it is smooth, flexible, and translucent. It is not difficult to outline corpuscles in series from those without a trace of color to forms well and clearly tinted. The colorless marrow cells with clear-bordered protoplasm appear to be the descendants of the solid lymphoid cells—the primary lymph-corpuscles, the protoleucocyte — which gradually becomes surrounded by a zone of homogeneous protoplasm. Certainly intermediate gradations can be seen between the forms figured at Fig. 7, *c*, and the smaller corpuscles at Fig. 7, *d*. The process of transformation of the nucleated red into the ordinary forms occurs, I believe, by the gradual disappearance of the nucleus, as shown at Fig. 8, *b*, 1, 2, and 3. It seems impossible to draw any other conclusion from a study of such cells, and the small granular remnants which they contain may be the sole means of distinguishing them from ordinary red corpuscles. Very many observers have recorded the fact of the migration of the nucleus from the cell, and it may be seen in all stages

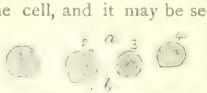

FIG. 10.—Blood of Embryo, Four Months. *a*, 1, 2, 3, 4. Nucleated red corpuscles; in 4 the same granular, disintegrated appearance of the nucleus as in marrow-cells. *b*, 1, myelocyte. 2, 3, 4, megalocyte. 5, granular red corpuscle.

of the process, as represented at Fig. 9, but I have not been able to convince myself that this is anything but a post-mortem change. Certainly in the fresh marrow there are not nearly so many corpuscles with nuclei partially extruded as in a specimen kept for twenty-four hours. Rindfleisch regards this as the normal mode of transformation, and we need additional careful observation on the point. In favor of the view that the nucleus undergoes disintegration is the fact that a similar process

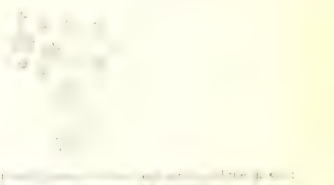
may be traced in the nucleated red blood-cells of the embryo, as shown at Fig. 10 *a*; and as the cells are identical in appearance, and probably in origin, this may be regarded as strong confirmative evidence. Bizzozero, whose careful study of this question entitles his opinion to the greatest consideration, regards the nucleated red corpuscle as a fixed and constant element derived, by fission, from pre-existing forms of the same kind, and not by any process of development from colorless cells of the marrow.

The nucleated red corpuscles are slightly larger than ordinary blood-corpuscles, and in size resemble the megalocytes which are usually abundant in the bone-marrow. Such a cell as is represented at Fig. 8 *b*, 4, differs in appearance from those at *b*, 1, 2, 3, solely in the absence of nuclear remnants. In the further process of development into the ordinary red corpuscle we must suppose condensation of the stroma and a change from a flattened cell to a biconcave disk. In anæmia the megalocytes which may be so abundant in the blood are to be regarded as imperfectly-formed corpuscles, which, from causes as yet unknown to us, have not attained their proper form.

Possibly in other ways the spleen and marrow elements may participate in the blood-formation. I have already referred to the process of budding which may be seen in certain of the red cells of the marrow (Fig. 3) and also of the spleen, and Malassez looks upon these gemmæ as capable of development into ordinary red forms.[1] The difficulty is one of interpretation; the process can be readily followed, but, as I mentioned, it is probably a physical change.

Within the large myeloplaques, and also in the elongated cells of the stroma of the marrow, there can be seen, occasionally, red corpuscles, which suggest *development*, not *disintegration*, inasmuch as the corpuscles are in smaller number and show no traces of degeneration. They are figured at 6 *a*, 1, 2, 3, from the spleen, and at 6 *b*, 3, from the marrow. I have been struck with the close resemblance of such cells to those in the subcutaneous tissue of the young rat, in which the process of intracellular development of red corpuscles can be readily traced, as shown by Mr. Schäfer. Fig. 6 *c* represents one of these connective-tissue corpuscles with four developing red cells in its protoplasm. It is quite possible that in the reversion to the embryonic or fœtal state of the bone-marrow these cells may resume their hæmatogenous function, which seems to be a widely-distributed property in the protoplasm of mesoblastic (parablastic?) elements.

The relation of the plaque to blood-formation is still undetermined, and the most diverse views prevail among those who have studied the question. Hayem argues that they are the true *hæmatoblasts*, and the red corpuscles arise directly from them, basing his opinion upon the following grounds: 1, The shape of the plaque is discoid, resembling a miniature blood-cell; 2, the faint tint of color which he says may be observed in them; 3, the remarkable gradations in size which they present, so that a complete series of forms may be traced from the smallest plaque to a common blood-disk; 4, their paucity in the healthy adult, their abundance in the young, and in all conditions in which blood-formation is rapidly going on; 5, their occurrence in the cells of the blastoderm. These views of Hayem have met with active opposition from a large majority of the observers who have studied the blood-plaque. I have never been able to detect coloration in the plaque, but, in the larger forms, the pale gray-white aspect of the protoplasm seems most distinct. I cannot see any connection between the blood-plaque and the ordinary microcyte, which is of a deep red tint, even when as small as the smaller plaques. The larger microcytes, 4–5 μ, which are usually paler in tint, have a homogeneous and distinctly colored stroma, precisely similar to the red corpuscle, and unlike plaques of the same size. Fig. 11 gives a representation of a



translucent, lymphoid cell or free nucleus.

group of elements from the spleen with the blood-plaques, five or six in number: 1, are of various sizes, and presented a pale, faintly granular protoplasm; at 2 were seen two microcytes, resembling more closely miniature blood-disks than the form represented at Fig. 1 and 4, but though resembling in size the larger plaques, the appearance is totally different, and forms intermediate between them are not seen. A strong point in Hayem's theory is the abundance of the plaques under the very conditions in which the corpuscular production goes on rapidly: (1) in the embryo and new-born, (2) after hemorrhages, (3) in the stage of convalescence from acute diseases. So, also, in chronic wasting diseases, and in certain forms of anæmia, their prevalence may be reasonably explained by failure to develop into more mature forms. We enter here the region of hypothesis, and it must remain for future observers to determine the precise position of the plaque in the development of the corpuscles. There is remarkable unanimity of opinion among those who have lately worked at the subject, to the effect that the evidence is at present altogether insufficient. Afanassiew is an exception, but he holds that the plaque develops into the nucleated red blood-corpuscle, the nucleus of which is in turn extruded and becomes a plaque.

The observations of the past ten or twelve years have led us away from the old view that the red cells are derived from the colorless corpuscles. Except in the mode I have indicated in the marrow, there is no evidence in favor of the conversion of the colorless blood-corpuscles into colored forms, and the opinion is gaining ground daily that they constitute separate elements with important functions quite apart from regeneration of the red cells. They constitute so many masses of primitive or basis protoplasm which may be called upon in the repair and reproduction of tissues and in the healing of wounds. They act as scavengers—*phagocytes*—in the removal of dead parts, or enclose injurious particles in their interior, and so render them inert. The leucocytes of the body have been compared to a standing army ready to resist invasion, and inflammation, in which they play such an important part, is but a battle by which they protect the organism against injurious agents, such as micro-organisms. The researches of Metschnikoff, Tavelowsky, and others, have so materially widened our conception of the functions of the colorless corpuscles, that we can regard with equanimity their displacement from the duty so long attributed to them of acting as progenitors of the red corpuscles.

After all, the most solid acquisition to our knowledge of the process of regeneration of the corpuscles, is the participation in the adult of the bone-marrow, and the development of the red corpuscles from its nucleated colorless cells. Here we seem to tread on a firm pavement of carefully observed and well-worked-out facts. There are minor details yet in dispute, which the next few years will see settled. Doubt and uncertainty still exist as to how far in the adult the spleen shares in the

[1] Creighton has observed the formation of colored corpuscles in the spleen by budding from nucleated cells; their walls, and in a few cases the nucleus, remained. Stone maintained (Seguin's Archives, vol. vi.) that the red cells developed by budding from the granular protoplasm of the adenoid reticulum of the spleen and lymph-glands.

process, and some good observers (Neumann) would deny altogether the post-natal formation of red corpuscles in it, but I think the evidence is sufficient to show that it shares this important function with the marrow.

We shall find, as our information on the subject deepens, that the regeneration of the corpuscles follows the laws governing the regeneration of tissues in general. In the adult body there are permanent and transitory tissue-elements, and to the latter the blood-corpuscles undoubtedly belong. The nutrition of the former is entirely interstitial, and does not involve any change in the element, when once fully developed. Of transitory elements the epidermic tissues are the best examples. The epithelium is in constant process of regeneration, and the shedding of the superficial cells is analogous to the destruction of the older red corpuscles. The new growth takes place by the constant fission and multiplication of the cells of the deeper part of the *rete mucosum*, and if the entire thickness of a portion of the epidermis is removed by accident, the remnant of the cells adherent to the corium repair the loss. Just so in the life-history of the blood-corpuscles, which are fleeting structures, like the epithelial cells, the hæmatogenous tissues—spleen, bone-marrow, lymph-glands—contain as permanent elements cells which, by fission, multiply and pass into the blood-current, more or less modified, as the red and white corpuscles.

The recent increase in our knowledge of the changes in the corpuscles in disease, and of the processes of reproduction, is an earnest of fuller information in the near future. A key to the solution of many problems in pathology will, I doubt not, here be found, but in seeking it let us not forget that the corpuscles float in the blood-plasma, the pathological relations of which await investigation, and offer a field for research which should be equally fruitful in advancing our knowledge of the ultimate processes of nutrition, and of those deviations from it which lie at the very root of so many chronic diseases.

INTUBATION OF THE LARYNX IN FIFTEEN CASES OF DIPHTHERITIC CROUP, IN THE SERVICE OF JOS. O'DWYER, M.D.

REPORTED BY DILLON BROWN, M.D.,

RESIDENT PHYSICIAN, NEW YORK FOUNDLING ASYLUM.

By intubation of the larynx we mean the insertion through the mouth into the larynx of a tube devised and perfected by Dr. Jos. O'Dwyer, of New York. The whole tube is completely contained within the larynx and trachea. The upper end rests upon the ventricular bands, and does not interfere with the functions of the epiglottis. The lower end is about half an inch from the bifurcation of the trachea.[1]

In all our cases we have uniformly inserted the tube to relieve suffering, without regard to the hopeless condition of the patient. No child has been allowed to die of layrngeal obstruction, although the tube was never inserted until the dyspnœa was most urgent.

CASE I.—Albert L——, aged three years and two months; diphtheria of larynx, pharynx, and posterior nares; albuminuria; recovery. (See report of case by Dr. O'Dwyer, *New York Medical Journal*, November 28, 1885.)

CASE II.—John E——, aged sixteen months; diphtheria of larynx and pharynx. Autopsy showed that pseudo-membrane extended from pharynx to the most minute bronchi. (See report of this case in *New York Medical Journal*, November 28, 1885.)

CASE III.—Herbert W——, aged one year and eleven months; diphtheria of larynx and posterior nares; severe rickets; double broncho-pneumonia; albuminaria; convulsions. This patient has rickets, and has never been able to walk or even stand alone. The post-nasal diphtheria began October 28th, and several days after this he had German measles, which lasted two days. He began to cough croupy November 4th, and signs of laryngeal obstruction soon showed themselves.

November 5th.—The dyspnœa grew progressively more severe, and at 5.15 P.M. it was excessive—extreme restlessness, deep sinking in of the lower end of the sternum, and cyanosis. Dr. O'Dwyer inserted one of his tubes, and the child, after coughing twenty minutes, fell into a quiet sleep. Temp., 102°; pulse, 138; resp., 24.

November 6th.—Slept quietly all night. He takes semi-solid food well, but has some difficulty in swallowing liquids. Temp., 103°; pulse, 192; resp., 36. P.M.: Temp., 103.2°; resp., 42. At 9.30 P.M. (twenty-eight hours after its insertion) the tube was coughed out and followed by a large amount of ropy, stringy mucus. It is rare for the tubes now in use to be coughed out, and in this case it was probably due to the thick, tenacious character of the mucus.

November 7th.—At 2 A.M. the characteristic croupy symptoms returned. 9 A.M.: Temp., 103°; pulse, 196; resp., 28. 7 P.M.: Temp., 103°; pulse, 180; resp., 48. The laryngeal obstruction gradually increased. At 7:30 P.M. the dyspnœa was extreme, and Dr. O'Dwyer was compelled to reinsert the tube (twenty-two hours after its removal).

November 8th.—Temp., 104°; pulse, 180; resp., 64. He is restless, and there are deep recessions above the clavicles and in the epigastrium. At noon the tube was removed, and a longer one inserted. The tube was coated with a tenacious ointment of nitrate of silver, ʒ j. to the ℥ j., in order to excite more vigorous coughing, which it did, and gave relief. P.M.: Temp., 102.1°; pulse, 150; resp., 36.

November 9th.—A.M.: Temp., 104.5°; pulse, 185; resp., 60. Slept well last night. Takes a fair amount of food. At 3 P.M. the tube was removed, four days after its first insertion. Physical examination shows an extensive double broncho-pneumonia. Much prostration. P.M.: Temp., 103.2°; pulse, 168; resp., 50.

November 10th.—A.M.: Temp., 103.3°; pulse, 168; resp., 54. The nasal discharge has stopped, and there has been no return of the croupy symptoms. P.M.: Temp., 103°; pulse, 168; resp., 60.

November 11th.—A.M.: Temp., 103.5°; pulse, 168; resp., 59. P.M.: Temp., 103.2°; pulse, 180; resp., 58. No signs of laryngeal obstruction.

November 12th.—Urine contains a large amount of albumin. No casts found. During the night he had a convulsion, and this morning another one, in which he died at 9.15 A.M., nearly three days after the removal of the tube, and the disappearance of all croupy signs.

Autopsy.—Extensive double broncho-pneumonia. Pleura hemorrhagic, and shows in places coating of fibrine. Interstitial emphysema of inner portion of left upper lobe. Bronchial glands enlarged. Trachea and larynx congested; trachea shows pseudo-membrane down to second division of bronchi. Kidneys not enlarged, markings fairly distinct. Liver congested. Other organs normal.

CASE IV.—Bessie L. H——, aged three years and two days; *diphtheria of larynx; albuminuria; double pneumonia.*

November 6th.—The first croupy signs appeared this morning, when she had a severe spasmodic attack of dyspnœa. After this had subsided there remained marked laryngeal obstruction, which grew worse very rapidly, and at 10.45 A.M. it was excessive. Dr. O'Dwyer inserted one of his tubes, which was expelled in fifteen minutes; but its use was followed by marked relief. Temp., 102°; pulse, 150; resp., 36. The char-

[1] For a description of the instrument and the case, see New York Medical Journal, August 1, 1885; and November 28, 1885; the Medical Record, February 21, 1885; Chicago Medical Journal and Ex., June and November, 1885; Archives of Ped., November, 1885; and Journal American Medical Association, February 6, 1886.

acteristic croupy symptoms returned immediately, and at 8 P.M. the child was suffering severely for air. Dr. O'Dwyer reinserted the tube, coated with a tenacious ointment of nitrate of silver, 3 j. to ℥ j., and left the string attached, by which it was removed in twenty minutes. It was applied in order to find out whether its astringent effect would enable the patient to dispense with the tube for several hours. But the obstruction returned rapidly, and the tube was reinserted at 10 P.M. The relief was immediate and the child fell asleep. Temp., 102°.

November 7th.—A.M.: Temp., 103°; pulse, 180; resp., 54. Sleeps quietly and takes a large amount of food. Physical examination shows abundant bronchial râles on both sides of the chest. Urine contains twenty per cent. albumin by bulk. P.M.: Temp., 105°; pulse, 160; resp., 54.

November 8th.—A.M.: Temp., 105°; pulse, 180; resp., 54. Urine contains 33⅓ per cent. of albumin by bulk. At 4.15 P.M. the tube was removed, but it was necessary to reinsert it at 5 P.M. She gradually failed, and at 10.30 P.M. died quietly—two and one-half days after first insertion of the tube.

Autopsy.—Larynx: Pale; some œdema of the folds; no pseudo-membrane. The lower half of the trachea contained a moderate amount of pseudo-membrane, extending into the second division of the bronchi. Trachea and bronchi intensely congested. Lungs: Œdema; extensive bronchitis; pneumonia of both lungs posteriorly. Kidneys: Congested, firm; markings distinct. Brain not examined. Other organs apparently normal.

Case V.—Sammy W——, aged three years and four months; tuberculosis; diphtheria of larynx, pharynx, and posterior nares; albuminuria; pneumonia.

November 21st.—Patient had a post-nasal and pharyngeal diphtheria, from which he was convalescent November 26th. But his temperature remained high and irregular, varying between 104.2° and 98° Fahr. Copious perspiration and frequently delirium. Pulmonary tuberculosis suspected.

December 13th.—Temp., 99°; pulse, 144; resp., 42. A croupy cough this morning. Pseudo-membrane has reappeared in the pharynx.

December 14th.—A.M.: Temp., 99.8°; pulse, 114; resp., 26. A fetid, bloody nasal discharge. P.M.: Temp., 102°; pulse, 168; resp., 24. Severe catarrhal conjunctivitis.

December 15th.—Otorrhœa. Pulse, 150; resp., 22.

December 22d.—All pseudo-membrane gone from pharynx.

December 28th.—A.M.: Temp., 103.5°; pulse, 180; resp., 36. P.M.: Temp., 101°; pulse, 180; resp., 23. Since last entry the temperature has varied between 105° and 101° Fahr. The cough has been more or less croupy. To-day the respiration became obstructed, and at 11.45 P.M. there was extreme dyspnœa. Dr. O'Dwyer inserted a tube, with complete relief. The boy coughed about fifteen minutes and fell into a quiet sleep.

December 29th.—A.M.: Temp., 102°; pulse, 144; resp., 30. P.M.: Temp., 103.1°; pulse, 180; resp., 28. No signs of laryngeal obstruction. At 11 P.M. (nearly twenty-four hours after its insertion) the tube was removed, and its calibre found free.

December 30th.—A.M.: Temp., 103.5°; pulse, 180; resp., 36. Slept fairly well last night. The dyspnœa slowly returned, and at 11 A.M. it was severe. The tube was reinserted (twelve hours after its removal), and gave immediate relief. P.M.: Temp., 104.5°; pulse, 168; resp., 34. At times marked delirium. Copious sweating of head and body. At 10.30 P.M. the tube was removed.

December 31st.—A.M.: Temp., 102.5°; pulse, 156; resp., 36. P.M.: Temp., 103.4°; pulse, 162; resp., 34. Moderate laryngeal obstruction.

January 1st.—A.M.: Temp., 103.5°; pulse, 156; resp., 29. The obstruction progressively increased, so that at noon it was excessive. At 12.10 (one and one-half day after its removal) the tube was reinserted, and the patient fell asleep in the nurse's arms. During the afternoon marked dyspnœa appeared. A larger and longer tube was inserted, and this gave relief. P.M.: Temp., 103.5°; pulse, 156; resp., 38. No dyspnœa.

January 2d.—A.M.: Temp., 104.8°; pulse, 156; resp., 60. At times delirious. Physical examination shows a broncho-pneumonia of left lower lobe; much prostration. Urine contains albumin, fifty per cent. by bulk, and hyaline and fine granular casts.

January 3d.—A.M.: Temp., 105.2°; pulse, 162; resp., 56, and irregular. At 10 A.M. the tube was removed (five and one-half days after its first insertion). P.M.: Temp.. 104.8°; pulse, 158; resp., 54. No dyspnœa.

January 4th.—A.M.: Temp., 105°; pulse. 156; resp., 66. About 3 P.M. the pulse was imperceptible, and the condition of the boy was that of extreme collapse. He rallied somewhat, and at 7 P.M. temp. was 104°; pulse, 156; resp., 76. No pseudo-membrane visible; no croupy symptoms.

January 5th.—Delirious all night. A.M.: Temp., 106.2°; pulse, 163; resp., 84. P.M.: Temp., 105°; pulse, 180; resp., 79. He slowly grew weaker and died quietly at 11 P.M.—two days and a half after the removal of the tube.

Autopsy.—Larynx, trachea, and bronchi, to about third division, contain a thin layer of pseudo-membrane. Superficial ulceration of mucous membrane of trachea, where lower end of tube came. Lungs: Lower two-thirds of left lung very firm, and marked infiltration of the small bronchi; recent diffuse pneumonia; less consolidation of the right lung, but in addition there are several tubercular cavities size of a bean; tubercular peri-bronchitis. Bronchial glands small, but contain tubercles. Kidneys: Moderate swelling of the epithelium of the convoluted tubules; size about normal. Heart, liver, and spleen normal. Stomach, intestines, and brain, not examined.

Case VI.—Katie H——, aged three years and four months; diphtheria of larynx and pharynx; pneumonia.

December 11th.—Yesterday her voice was hoarse. During the night she became croupy, and to-day the cough and inspiration present the characteristic croupy signs. Temp., 98°; pulse, 144; resp., 30. Tonsils and fauces are red and swollen, but no pseudo-membrane can be seen. Cervical glands enlarged. No nasal discharge. The dyspnœa grew progressively more severe, so that at 3.35 P.M. Dr. O'Dwyer inserted the tube, which gave immediate relief. P.M.: Temp., 102.2°; pulse, 138; resp., 34.

December 12th.—A.M.: Temp., 103.8°; pulse, 150; resp., 48. Both tonsils covered with pseudo-membrane.

December 13th.—A.M.: Temp., 102°; pulse, 150; resp., 38. P.M.: Temp., 103.2°; pulse, 174; resp., 60. Physical examination shows bronchial respiration on both sides of chest. A few subcrepitant râles on right side after coughing. Nostrils dilate on inspiration.

December 14th.—About 2.30 A.M. she became restless and had some dyspnœa; but she soon grew quiet, and died at 4 A.M.—two days and a half after insertion of the tube.

Autopsy.—Pharynx, larynx, trachea, and bronchi, to fifth division, contain pseudo-membrane. In the lungs the membrane can be traced to the fifth division in some bronchi, and only to the second in others. Glands along trachea, above bifurcation, enlarged, and several of them cheesy. Lungs: Much œdema and congestion. Small masses of pneumonia. Pleural exudate of delicate adhesions, more marked over the seat of the pneumonia. Spleen, liver, and kidneys normal. Mesenteric glands enlarged. Moderate catarrh of the intestines.

Case VII.—Vincentine W——, aged three years and six months; diphtheria of larynx and posterior nares; pertussis; pneumonia; albuminuria. Two weeks ago she had a broncho-pneumonia, from which she is now convalescent. She has whooping-cough.

December 21st.—The characteristic croupy symptoms were well marked at noon. The pharynx is swollen and red, but no membrane can be seen. P.M.: Temp., 102°; pulse, 156; resp., 21.

December 22d.—P.M.: Temp., 102°.

December 23d.—A.M.: Temp., 99.8°; pulse, 75; resp., 25. P.M.: Temp., 101°; pulse, 168; resp., 30. A bloody, fetid nasal discharge. No pseudo-membrane is visible. Vomits frequently, but takes a good amount of food. At noon she coughed up a large piece of pseudo-membrane.

December 24th.—A.M.: Temp., 100.2°; pulse, 168; resp., 36. The dyspnœa grew progressively worse, so that at 2 P.M. it was excessive; extreme restlessness, cyanosis, and deep falling in of the lower end of the sternum. The tube was inserted and gave immediate relief. There was coughed up through the tube a large cylinder of pseudo-membrane, with three branches. P.M.: Temp., 104.2°; pulse, 180; resp., 48.

December 25th.—A.M.: Temp., 102°; pulse, 156; resp., 42. P.M.: Temp., 103.6°; pulse, 192; resp., 48. Slept quietly last night. Pseudo-membrane in the pharynx. Much prostration. Urine contains albumen, fifty per cent. by bulk, and a few granular casts.

December 26th.—At 1.30 A.M. the tube was removed and found free from obstruction. The dyspnœa returned so rapidly that the tube was immediately reinserted, but without relief. It was removed and a cast of the trachea expelled, but the dyspnœa was not relieved until the tube was put back. She died quietly at 4 A.M., thirty-eight hours after its first insertion.

Autopsy.—Larynx, pharynx, and trachea, to finest bronchi, contain pseudo-membrane. Lungs: Bronchial glands large and cheesy; tubercular peri-bronchitis and some diffuse tubercular tissue of right lung; also some recent pneumonia of both lungs; interstitial emphysema of left anterior superior lobe. Kidneys large and boggy; cortex thick, and striations indistinct. Other organs appeared normal.

Case VIII.—Adelaide I——, aged three years and seven months; diphtheria of larynx, pharynx, and posterior nares; albuminuria; recovery.

December 28th.—Post-nasal and pharyngeal diphtheria began December 25th. Last night the characteristic croupy cough and respiration began. A.M.: Temp., 100.6°; pulse, 150; resp., 30. The dyspnœa grew progressively more severe, and at 6.40 P.M. it was excessive. I inserted the tube and it gave immediate relief. P.M.: Temp., 100.5°; pulse, 150; resp., 28.

December 29th.—A.M.: Temp., 103.8°; pulse, 174; resp., 60. Slept quietly all night. Takes a fair amount of food. P.M.: Temp., 102.3°; pulse, 162; resp., 42.

December 30th.—A.M.: Temp., 101°; pulse, 162; resp., 36. No membrane is visible in the pharynx. At 6.30 P.M. a piece of pseudo-membrane was expelled through the tube. P.M.: Temp., 102.5°; pulse, 150; resp., 36.

December 31st.—A.M.: Temp., 104.5°; pulse, 180; resp., 42. At 7.30 A.M. the tube was expelled, and its calibre found free of obstruction. The dyspnœa returned quickly and soon became excessive—extreme restlessness, cyanosis, and deep sinking in of the lower end of the sternum. At 1 P.M. she was comatose. I quickly inserted the tube, which gave immediate relief to the dyspnœa, but caused no coughing. She remained unconscious until 4 P.M., when she began to rally. In all our cases we have uniformly waited until the dyspnœa was excessive before inserting the tube. The operation is done so quickly, requiring only a few seconds, that we have been able to defer the operation longer than we would have dared to do if we intended to resort to tracheotomy. Thus we have had four recoveries from diphtheritic croup without resorting to any interference; and in all of these cases the dyspnœa was well pronounced, and would have urgently called for tracheotomy. P.M.: Temp., 104.6°; pulse, 164; resp., 56. No dyspnœa, and the patient is bright and comfortable. Urine contains twenty per cent. albumen by bulk, and hyaline and fine granular casts.

January 1st, 1886.—Slept quietly last night. The tube was removed at 9.25 A.M.—three days and fifteen hours after its first insertion. A.M.: Temp., 102.6°; pulse, 138; resp., 32. P.M.: Temp., 99.8°; pulse, 132; resp., 34.

January 2d.—A.M.: Temp., 100°; pulse, 144; resp., 30. P.M.: Temp., 101.2°; pulse, 144; resp., 27. A croupy cough, but no dyspnœa.

January 3d.—A.M.: Temp., 101°; pulse, 126; resp., 32. P.M.: Temp., 101°; pulse, 135; resp., 46. No dyspnœa. Voice hoarse and inspiration noisy.

January 4th.—A.M.: Temp., 99.8°; pulse, 132; resp., 36. P.M.: Temp., 99.6°; pulse, 132; resp., 30.

January 5th.—A.M.: Temp., 99.6°; pulse, 144; resp., 36. P.M.: Temp., 100°; pulse, 126; resp., 24.

January 6th.—A.M.: Temp., 98.9°; pulse, 138; resp., 28. P.M.: Temp., 99.8.° No croupy symptoms. Respiration noisy when asleep.

January 7th.—Temp., 99.5°; pulse, 132; resp., 30. Convalescent.

January 11th.—Slight paralysis of the muscles of both legs.

January 14th.—She was out of bed and dressed.

January 18th.—She regained her voice—seventeen days after the removal of the tube.

Case IX.—Eliza W——, aged eleven months; diphtheria of larynx and pharynx; albuminuria.

December 22d.—A.M.: Temp., 102.8°; pulse, 168; resp., 60. The pillars of the fauces, the uvula, tonsils, and posterior wall of the pharynx covered with pseudo-membrane. The characteristic croupy symptoms are well marked. Miserable condition. The dyspnœa grew severe, and although it was a hopeless case from the beginning, the tube was inserted to relieve the suffering. At 11.30 A.M. I inserted the tube. The child immediately fell into a quiet sleep, and the respiration dropped from 60 to 48 per minute. P.M.: Temp., 104.8°; resp., 96. At 9 P.M. (nine and one-half hours after its insertion) the tube was removed and its calibre was free. The dyspnœa returned so rapidly that the same tube was put back at 9.30 P.M. Temp., 105.6°; resp., 66. Urine contains albumen fifty per cent. by bulk.

The dyspnœa returned in a few hours, and at 2 A.M., December 23d, she died with severe dyspnœa (fourteen and one-half hours after the insertion of the tube).

Autopsy.—A thin layer of pseudo-membrane in the trachea, ending at the bifurcation. Lungs: Intense bronchitis and œdema; no consolidation. Marked œdema of the anterior mediastinum. Kidneys: Markings slightly indistinct. Larynx: Swelling of the epiglottis, and ary-epiglottic folds overlapping the aperture of the tube. This condition never having occurred before, it was not suspected. The introduction of a larger-headed tube would have removed the difficulty. The secondary dyspnœa in this case was believed to be due to the extension of the membrane into the bronchial tubes. This dyspnœa always occurs when the bronchi are plugged by pseudo-membrane to any extent.

Case X.—Julia Mc——, aged three years and three months; diphtheria of larynx and pharynx; albuminuria; double pneumonia.

December 24th.—Last night about 8.30 P.M. the characteristic croupy symptoms appeared. A.M.: Temp., 100.6°; pulse, 150; resp., 20. P.M.: Temp., 101.8°; pulse, 150; resp., 24. No pseudo-membrane visible in the pharynx. The laryngeal obstruction grew progressively worse. At 10.30 P.M. a piece of pseudo-membrane was coughed out, but it gave no relief. At 10.40 P.M. the dyspnœa was extreme, and the tube was inserted. The child fell into a quiet sleep and rested well all night.

December 25th.—A.M.: Temp., 103°; pulse, 168; resp., 28. P.M.: Temp., 103.8°; pulse, 180; resp., 36. No dyspnœa. Coughed a small piece of membrane from the trachea through the tube.

December 26th.—At 1.30 A.M. the tube was removed, and its calibre found free. Temp., 104.6°; pulse, 178; resp., 42. The obstruction returned rapidly, and at 6.35 P.M. (seventeen hours after removal of the tube) it was so severe that the tube was reinserted. Immediate relief to the dyspnœa. P.M.: Temp., 103.2; pulse, 168; resp., 44.

December 27th.—A.M.: Temp., 104.5°; pulse, 168; resp., 48. P.M.: Temp., 104.5°; pulse, 168; resp., 46. Cheeks flushed and nostrils dilate. Pseudo-membrane visible in the pharynx for the first time. Urine: Sp. gr., 1.028; acid; no casts; albumen, thirty-three and one-third per cent. by bulk. At 9.45 the tube was removed, but the dyspnœa returned so rapidly that it was reinserted in half an hour. She gradually failed, and at 10.30 P.M. she died comatose—three days after the first insertion of the tube.

Autopsy.—Pseudo-membrane in the pharynx and larynx. There is a thick, tenacious cast of pseudo-membrane from the tip of the epiglottis to the most minute bronchi. Lungs: Pneumonia of posterior portion of both lungs. Pleura shows points of hemorrhage. Glands moderately enlarged and dusky. Kidneys show some cloudy swelling. Heart, liver, spleen, stomach, and intestines normal.

Case XI.—Rose M. T——, aged four years and eight months; diphtheria of larynx and pharynx; albuminuria; recovery. Just recovering from whooping-cough. December 28th she had a pharyngeal diphtheria, from which she was convalescent January 3d.

January 5th.—Last night she was hoarse, and this morning the characteristic croupy symptoms appeared. The pharynx is swollen and red, and on the left tonsil there has reappeared a patch of pseudo-membrane. A.M.: Temp., 100.5°; pulse, 158; resp., 30. P.M.: Temp., 99.5°; pulse, 132; resp., 30. Urine contains albumen, fifty per cent. by bulk.

January 6th.—A.M.: Temp., 99 5°; pulse, 120; resp., 28. P.M.: Temp., 100.6°; pulse, 156; resp., 26. Pharynx covered by dark gray, sloughy pseudo-membrane. A small piece of membrane expelled while coughing. Well-marked laryngeal obstruction, which has increased slowly and progressively. At 11.20 P.M. it was severe and the tube was inserted. She coughed about half an hour and then fell asleep. After the insertion of the tube the patient usually coughs about fifteen minutes and then falls into a quiet sleep—the dyspnœa is completely relieved. The coughing is of much benefit by aiding the expulsion of mucus, and the tube is often coated with an ointment of nitrate of silver for that purpose.

January 7th.—P.M.: Temp., 101°; pulse, 138; resp., 38. Slept quietly all night; no dyspnœa. She does not take food as well as usual. When the tube is in the larynx the patients usually take semi-solid food, as soft-boiled eggs, mush, ice-cream, etc., from the beginning; but it is twenty-four hours, as a rule, before they learn to take liquid food easily.

January 8th.—A.M.: Temp., 100.6°; pulse, 108; resp., 36. P.M.: Temp., 101.5°; pulse, 138; resp., 34.

January 9th.—A.M.: Temp., 101.2°; pulse, 144; resp., 32. Tube removed at noon, two and a half days after its insertion. P.M.: Temp., 101.4°; pulse, 150; resp., 36; slight croupy cough; no dyspnœa.

January 10th.—A.M.: Temp., 101°; pulse, 162; poor condition; no dyspnœa; urine contains fifty per cent. albumen by bulk; feet, hands, and face are much swollen. On great effort, she can phonate (one day after the removal of the tube).

January 11th.—A.M.: Temp., 99.8°. P.M.: Temp., 99.2°.

January 12th.—A.M.: Temp., 100°; pulse, 126; resp., 30. P.M.: Temp., 99.8°; urine contains no albumen; œdema of hands and feet gone; good, clear voice. Well.

Case XII.—Eva O——, aged one year and two days; diphtheria of larynx, varicella; miserable condition.

January 15th.—The baby is in miserable condition. It was born prematurely and has never thrived. There has been a well-marked croupy cough and respiration since yesterday afternoon. The dyspnœa gradually increased until noon, when it was excessive; rapid respirations, restless, dark color of skin, and deep falling in of the lower end of the sternum. The tube was inserted and relieved the dyspnœa immediately; but the child was so exhausted that the presence of the tube caused only a few feeble coughs; fetid otorrhœa. The case was hopeless from the beginning, and the tube was inserted only to relieve the suffering. No pseudo-membrane visible in the pharynx; physical examination shows a double pneumonia. P.M.: Temp., 104.5°; resp., 64. The baby gradually failed, and at 6 A.M., January 16th, quietly died, eighteen hours after the insertion of the tube.

Autopsy.—Epiglottis normal. No pseudo-membrane in the larynx, except over the ventricles. Trachea lined by a thin layer of pseudo-membrane; membrane extends to the third division of the bronchi. Lungs: Bronchopneumonia of lower portion of both lungs, more marked on left side. The lower end of the tube came within half an inch of the bifurcation of the trachea.

Case XIII.—Minnie V——, aged three years and nine months; diphtheria of larynx and pharynx; pertussis; recovery. Patient is in poor condition and has pertussis. January 3d, she had diphtheria of pharynx, from which she was apparently well January 13th.

January 14th.—P.M.: Temp., 100°; urine normal; well-marked croupy symptoms appeared last night. The dyspnœa grew progressively worse, so that at 9 P.M. the tube was inserted. At 9.40 P.M. she was asleep and all the dyspnœa gone. Pulse, 134; resp., 26. Good respiratory murmur over both lungs.

January 15th.—A.M.: Temp., 100.5°; pulse, 126; resp., 31. P.M.: Temp., 101.8°; pulse, 120; resp., 48. There was a small patch of pseudo-membrane in the pharynx yesterday, but it has disappeared to-day; no dyspnœa.

January 16th.—A.M.: Temp., 99°; pulse, 156; resp., 42; sleeps well, takes food well and is comfortable. At noon the tube was removed—thirty-nine hours after its insertion. P.M.: Temp., 101.2°; pulse, 132; resp., 22. The croupy signs have returned, but there is no dyspnœa.

January 17th.—A.M.: Temp., 99.5°. P.M.: Temp., 99.8°; pulse, 120; resp., 20.

January 24th.—Since last entry she has improved rapidly. No return of the dyspnœa, and the temperature has not been above 101° Fahr.; good voice. Well.

Case XIV.—Emily E——, aged three years and five months; diphtheria of larynx and pharynx.

January 16th.—This morning the characteristic croupy symptoms appeared. There is a large patch of pseudo-membrane in the pharynx. A.M.: Temp., 102.2°; pulse, 138; resp., 40. P.M.: Temp., 102.5°: pulse, 156; resp., 28. The laryngeal obstruction is well marked. Severe epistaxis.

January 17th.—The dyspnœa grew progressively worse, and at 5 A.M. it was excessive. I inserted a tube and it gave immediate relief. She vomited freely and expelled a piece of pseudo-membrane while coughing. Pulse, 180; resp., 36. At 9 A.M.: Temp., 104.5°; pulse, 180; resp., 73. Although the respiration is rapid there is no dyspnœa. Physical examination of the chest is negative. P.M.: Temp., 105°; pulse, 192; resp., 72. At 7.30 P.M. the tube was removed to see if its calibre was free. The tube was clear, and at 7.45 P.M. it was reinserted, coated with an ointment of nitrate of silver to excite coughing. Pulse over 200. She gradually failed and died quietly at 2.30 A.M., January 18th—twenty-one and a half hours after the insertion of the tube.

Autopsy.—Pharynx, larynx, trachea, and bronchi to nearly the base of the lung, contain macerated pseudo-membrane. Tonsils excavated. Lungs: Beginning pneumonia in both; marked œdema; pus easily ex-

pressed from bronchi; bronchial glands enlarged and dusky. Liver and kidneys congested. Heart normal. Intestines: Peyer's patches moderately congested and swollen; solitary follicles pigmented. Urine drawn post-mortem contains no casts.

Case XV.—Liza W——, aged five months and twelve days; diphtheria of larynx and posterior nares; diarrhœa. She had varicella January 14th.

January 20th.—About 8 P.M. yesterday the first signs of croup appeared, since which time the dyspnœa has gradually increased. Severe diarrhœa. P.M.: Temp., 101.4°; resp., 50. Fetid, bloody nasal discharge.

January 21st.—At 3.30 A.M. the dyspnœa was so severe that a tube was inserted. It gave immediate relief to the dyspnœa, but the baby was so exhausted that the presence of the tube caused no coughing. The child fell asleep and all dyspnœa disappeared. A.M.: Temp., 104.4°; resp., 84. Cheyne-Stokes respiration.

January 22d.—She gradually failed, and died quietly from exhaustion at 1 A.M.—twenty-one and a half hours after the insertion of the tube. After death the tube was removed and found clear.

Autopsy.—Larynx, trachea, and bronchi (left) contain pseudo-membrane, going from root to base of lung. Less pseudo-membrane in the bronchi of the right lung. Lungs: Well-marked double broncho-pneumonia. Kidneys, heart, liver, and spleen seem normal. Intestines: Peyer's patches swollen; mesenteric glands enlarged.

The autopsies were made by Dr. W. P. Northup, pathologist to the asylum.

To recapitulate:

1. All the cases were among the class of children called foundlings.

2. The tube was inserted in *every* case of severe laryngeal obstruction that occurred in the asylum without regard to its hopeless character.

3. One-third of the cases were babies aged sixteen, twenty-three, eleven, twelve, and five months respectively, an age at which recovery after tracheotomy is extremely rare.

4. Two (Cases V. and VII.) had tuberculosis, a disease which is in itself absolutely fatal.

5. One (Case III.), a rickety child, died of uræmic convulsions three days after the disappearance of all laryngeal obstruction.

6. The tube requires no attention, after its insertion, to keep it clean, and if a piece of pseudo-membrane should close it (which is not likely to happen), the tube is held in place so loosely that it would be immediately expelled.

7. The inspired air is warm and moist. This prevents drying of the secretion in the tube.

8. The head or shoulder of the tube does not rest upon the vocal cords, but just above them on the ventricular bands. There is never any ulceration of the cords, but slight ulcerations may be produced by the head and the lower end of the tube, when retained for a long time. This can do no harm.

9. There is not the slightest danger of the tube slipping through into the trachea.

10. In most cases semi-solid food is taken well from the beginning; but it usually takes twenty-four hours for the child to learn to swallow liquids. Occasionally, in very young children, it is necessary to feed them through a tube.

11. The mouth-gag is intended only for children who have back teeth. In babies there is no difficulty in keeping the mouth open with the finger.

A Gift from Medical Students.—The students of medicine and pharmacy of Marseilles have presented to the hospital administrators the sum of nearly twenty thousand francs, to be applied to the erection of isolating wards for the reception of children suffering from contagious diseases. The money was the net proceeds of a series of balls given by the students in recent years.

REMARKS UPON SOME OF THE PHYSICAL SIGNS OBSERVED IN EXAMINATION OF THE CHEST.[1]

By R. C. M. PAGE, M.D.,

INSTRUCTOR IN THE DEPARTMENT OF DISEASES OF THE CHEST AND GENERAL MEDICINE, NEW YORK POLYCLINIC, AND ATTENDING PHYSICIAN FOR DISEASES OF THE CHEST, NORTHWESTERN DISPENSARY, NEW YORK CITY.

The history of Inspection and Palpation as methods of procedure in the physical examination of the chest appears to be unknown. The same may be said of Mensuration, although some of the instruments used for that purpose, such as the stethometer, cyrtometer, and the like, are comparatively recent inventions.

Thoracic percussion, however, was discovered by Auenbrugger in 1753, while engaged in the study of empyema and the indications for thoracentesis in that disease. He was born in Gratz, Styria, in 1722, and practised in Vienna, where he died in 1809. He performed only immediate percussion, and published his views on that subject in 1761. Piorry, of Paris, invented the pleximeter in 1828, and was the first to practise mediate percussion. He was the first also to draw attention to the increased sense of resistance which accompanies the dull percussion sound. To Walshe, of London, more recently, is due the honor of having been the first to call attention to the all importance of pitch in the clinical examination of the heart and lungs. Skoda was the first to describe tympanicity as a quality of percussion resonance. That occurred in 1839, and in 1841 Wintrich invented the percussion hammer. Since that time, Guttmann, of Berlin, Gerhard, Geigel, and others have called attention to variations in the pitch of tympanitic resonance. Flint, of New York, first applied the term vesiculo-tympanitic (called bandbox by Biermer) to the exaggerated percussion resonance of emphysema, and broncho-vesicular, instead of rude or harsh, to the respiratory murmur obtained over incomplete consolidation of lung-tissue, as observed in incipient phthisis.

Hippocrates (460–375 B.C.) was the inventor of succussion, by which means the splashing sound characteristic of pneumo-hydrothorax is detected. He may, therefore, be said to have been the first to make use of auscultation, but to a very limited extent. But Laennec, of Paris, invented the stethoscope in 1816, and was the first to give to auscultation the value which it now possesses. Honoré, a contemporary with Laennec, first observed the pleuritic friction sound as a physical sign, but its true pathological significance was afterward fully pointed out by Raynaud.

Trousseau, of Paris, first brought before the profession in a practical manner the operation of paracentesis thoracis (thoracentesis) in cases of extensive pleuritic effusions, whether of serum or pus. After his death it fell into disuse, but was revived in 1852 by Dr. Bowditch, of Boston, Mass., who clearly pointed out the indications for the operation. More recently, by means of the hypodermic syringe, the existence and character of pleuritic effusions can be established with certainty. In 1840 Drs. Cammann and Alonzo Clark, of New York City, invented auscultatory percussion. It is especially useful in the diagnosis of thoracic aneurism, but may also be used for accurately determining the boundaries of the heart, liver, and other organs of the body.

Other less important procedures in physical diagnosis are autophonia, the method by musical vibrations, and phonometry. Autophonia was first brought into notice by the late M. Hourmann, who "connected peculiarities in the resonance of the observer's own voice (as he speaks with the ear applied to the chest directly, or with the intervention of the stethoscope) with certain definite conditions of density of the parts beneath." The method by musical vibrations originated with Drs. Stone and Grabham (London *Lancet*, vol. i., 1867, p. 114), and consists in "communicating a musical impulse to the air in the

[1] Read before the New York Medical and Surgical Society, New York City, February 17, 1886.

bronchial passages by forcibly inspiring through a tube or pitch-pipe containing a free reed. The note emitted is directly conveyed to the parts under observation." Phonometry is a new method described by Baas. It "consists in placing a vibrating tuning-fork on the surface of the chest or abdomen, and determining, by the intensity or feebleness of the tone it gives, the condition of the subjacent organs." The best instrument for this purpose is Blake's tuning-fork, with a small spring hammer attached.

Although physical diagnosis approaches nearer, perhaps, to an exact science than any other branch of the practice of medicine, yet, even in this, eminent authors sometimes make such conflicting statements about the same thing that one is left in doubt as to the real condition. In emphysema, for instance, the apex beat of the heart is displaced, according to some authors, downward and inward. According to Niemeyer and others, it is carried downward and outward. Niemeyer (seventh Germ. ed., American trans., vol. i., p. 126) says that "as a natural consequence of depression of the diaphragm in emphysema, the oblique position of the heart becomes more horizontal, and its apex lies farther out." According to my own experience that is the rule, the displacement downward and inward, being the exception. The epigastric pulsation is due to the right ventricle, which has been lowered and hypertrophied—the latter condition having been brought about by obstruction to the circulation of the blood in the lungs. Sometimes the apex-beat in this disease is so obscured by lung-tissue spread over it that it is difficult, and even impossible, to find it.

The sound produced by percussing the healthy chest is variously termed, by different authors, normal vesicular resonance, normal pulmonary resonance, and normal percussion resonance. I prefer the latter expression, it being in more marked contradistinction to that of normal *vocal* resonance.

The note of any percussion resonance consists of four properties or elements: 1, Duration (length); 2, intensity (amount); 3, pitch; 4, quality (timbre). Pitch marks the different degrees of elevation of sounds elicited by percussing different substances. Liquids emit, under percussion, a higher-pitched sound than solids, and solids than gases (Walshe: "Diseases of the Lungs," fourth edition, p. 48). Quality marks the different kinds of sounds that are characteristic of different substances. Thus flatness is characteristic of the presence of fluid, dulness of solidification, and tympanicity of a cavity with tense walls and containing air. Walshe and some others are right, I think, in regarding pitch as the most important property of a percussion note, the duration and intensity being secondary to and varying with it. The lower the pitch the longer will be the duration, and the greater the intensity (amount, volume). On the other hand, the higher the pitch the shorter will be the duration of the note and the less the intensity. Skoda, however, pronounces pitch to be an attribute of chest-sounds of no value, and Guttmann ("Handbook of Physical Diagnosis," p. 60, William Wood & Co., New York, 1880) regards intensity as the most important.

To distinguish differences in pitch, especially when slight, is not within the reach of every one. It is simply a natural gift, and belongs to those who are born with what is called an ear for music. Even then it requires cultivation and practice.

Authors differ as to whether the pitch of percussion resonance at the end of a full inspiration is higher or lower than it is at the end of a full expiration. According to Walshe (*op. cit.*, p. 62) it is higher at the end of a forced expiration. Guttmann, Da Costa, and Flint state that it is higher at the end of a forced inspiration, owing to increased tension of the chest-walls and lung-tissue. A chest with little expansive power may be made very tense on forced inspiration without increasing the volume of air in proportion. Here the pitch of the percussion note would be higher at the end of a full inspiration. If volume exceeded tension we would get a lower note. Flint ("Manual," pp. 58, 59, Lea Brothers & Co., fourth edition, 1885) says that "the instances of disease, however, are exceedingly rare in which such nicety of discrimination is important."

In the same way we find different statements about the pitch of the percussion resonance in emphysema. Walshe (*op. cit.*, p. 328) says it is lowered, while Flint (*op. cit.*, p. 165) says it is more or less raised. The truth is, the pitch in emphysema is sometimes lowered and sometimes raised, but the quality remains the same. Especially do we find it raised in cases of long standing and complicated with old bronchitis and peribronchial thickening, together with marked rigidity of the chest-walls.

If Walshe's statement (*op. cit.*, p. 48) be correct, and I believe it is, that, other things equal, the greater the quantity of air in the part struck, the lower the pitch, we have one important fact toward explaining variations in the pitch of tympanitic resonance. The bass-drum emits tympanitic resonance on percussion, and so does the snare-drum. But the pitch of the former is lower than that of the latter. The pitch also varies with the amount of tension. It may be higher or lower, therefore, than the pitch of normal percussion (pulmonary, vesicular) resonance. According to Guttmann (*op. cit.*, p. 72) the pitch of tympanitic resonance obtained by percussing pulmonary cavities is higher when the mouth is open, lower when it is shut, and lower still when the nostrils are closed—provided the cavity communicates freely with a large-sized bronchial tube.

In percussion resonance, as already said, the lower the pitch the greater, as a rule, will be the intensity of the note and the longer its duration. How is it in the case of vocal resonance? The same law applies to *normal* vocal resonance, but in *bronchial* vocal resonance (bronchophony), as obtained in case of solidified lung-tissue, the pitch is raised, the duration is shortened, but the intensity, as a rule, is markedly increased. The change in pitch is due to the change the voice makes from one medium to another—from normal tissue to solidification—in its transmission to the chest-walls (Walshe, *op. cit.*, p. 147). But it is raised all the same, and with that the intensity is increased instead of being diminished, or just the reverse of what occurs in percussion resonance. The fact appears to be that in percussion resonance, or normal vocal resonance, when the pitch is low, the intensity is greater in the sense of *volume;* whereas in bronchophony, although the pitch of the voice-sound has been raised *in transitu*, the intensity has been increased in *concentrated amount*, due to increased conduction, by reason of consolidated lung-tissue.

The fact that in bronchophony the intensity of the vocal resonance is increased though the pitch be raised, should not lead to the error of supposing that a high-pitched or loud, shrill voice is most favorable for the production of any kind of vocal resonance. On the contrary, a loud, harsh, low-pitched voice will, other things equal, give not only better normal vocal resonance, but also more intense bronchophony than will a loud, shrill (high-pitched) voice.

What is true of bronchophony is also true of bronchial breathing. Here also the pitch is higher and the duration shorter, but the intensity (concentrated amount) is increased.

The pitch of normal percussion resonance is higher, as a rule, in the right subclavicular (infraclavicular, supramammary) region than the left. Walshe ("Diseases of the Lungs," p. 64, fourth edition) attributes this to the greater development of muscle on the right side, as is generally the case. When the normal pitch is higher on the right side, in the absence of such preponderance of muscular tissue on that side, as in the case of a left-handed person, he offers no explanation.

According to Flint ("Manual," p. 51, fourth edition,

1885) the raise in the pitch of percussion resonance in the subclavicular region is due to the combination of the vesicular with a tympanitic quality toward the sternum, the latter being derived from the primary and secondary bronchi. Whether it be this or the presence of bronchial tubes occupying space that would otherwise be taken up by vesicular tissue, the fact that the right primary bronchus is larger and higher up than the left, would cause the pitch to be slightly higher in the right than the left subclavicular region.

Besides this, the right lobe of the liver as a solid base for the right lung, may possibly have some influence toward raising the pitch of the right subclavicular (infraclavicular, supramammary) region, as opposed to the large end of the stomach in relation to the left lung. Da Costa and Loomis simply mention the fact, while Guttmann ("Handbook of Physical Diagnosis," p. 68, William Wood & Co., New York, 1880) states that "on the right the pitch is usually deeper (lower) than on the left, though occasionally the reverse condition is met with." Such variations, according to the same author, possess no diagnostic value, as they depend only on the physiological differences in the tension of the chest-wall. According to my own observations the pitch of the normal percussion resonance is slightly higher in the right than in the left subclavicular region, as a rule. When the reverse occurs it is the exception.

All the authors quoted thus far, except Guttmann, state that the normal respiratory murmur in the right subclavicular region is more bronchial in character than on the left side. In the former, according to Loomis ("Physical Diagnosis," p. 35, William Wood, New York, 1883), the pitch of both inspiration and expiration is higher, less vesicular, and the expiration more pronounced and prolonged than in the latter. Guttmann states, erroneously I think, that it is simply more intense sometimes on one side, sometimes on the other. Flint (*op. cit.*, p. 87) calls this breathing in the right subclavicular region "the normal broncho-vesicular respiration," and says that "these several modifications of the respiratory murmur in the infraclavicular region are marked in proportion as the sounds are studied near the sternum, that is, over the site of the primary bronchi." In other words, the right primary bronchus, being larger than the left and higher up, gives the broncho-vesicular character to the normal respiratory murmur in the right subclavicular region which is not to be found in the left.

The reason why normal vocal fremitus is felt with greater intensity on the right side than on the left is, I believe, correctly given by Guttmann (*op. cit.*, p. 49) and others, and that is because the right bronchus is larger than the left. Moreover, according to Gray ("Anatomy," p. 850, Henry C. Lea's Son & Co., Philadelphia, 1883), the septum between the two primitive bronchi is situated to the left of the median line, so that foreign bodies entering the trachea naturally drop into the right bronchus. It is reasonable, therefore, to suppose that a greater amount of voice-sound would be conducted to the right than to the left side of the chest. Moreover, the left bronchus passes under the arch of the aorta, which may tend to interrupt the vibrations in that tube. The same reasons may be given why the normal vocal resonance is more marked on the right side than the left, as was first noticed by Stokes, of Edinburgh, Scotland.

In reviewing the points of disparity between the physical signs, as obtained in the right and left subclavicular regions of the healthy chest, we note the following: 1. Inspection is chiefly negative. 2. Palpation gives more fremitus on the right side. 3. The pitch of the percussion note is, as a rule, slightly higher on the right side. 4. Upon auscultation we find normal broncho-vesicular respiratory murmur and more intense vocal resonance on the right side. In other words, we have in the right subclavicular region of a healthy chest some physical signs which resemble very closely those of incomplete consolidation of lung-tissue, as seen in incipient phthisis. All that is wanting to make out this latter disease are localized subcrepitant râles or the mucous click. "Without a practical knowledge of these points of disparity," says Flint (*op. cit.*, p. 88), "error in diagnosis can hardly be avoided."

Walshe (*op. cit.*, p. 26) states that "as a general rule sounds of high pitch give *relatively* most vocal resonance, sounds of low pitch most fremitus." In other words, a high-pitched voice may give a fair amount of vocal resonance without any fremitus. This does not mean that a high-pitched or loud, shrill voice gives better vocal resonance than a loud, low-pitched voice, for farther on he says (*op. cit.*, p. 126) that, "*cæteris paribus*, the natural (vocal) resonance is marked in proportion to the graveness of the voice." Flint (*op. cit.*, p. 91) states that the "intensity (of normal vocal resonance) depends greatly on the loudness and lowness in pitch of the voice of the person examined. The resonance is notably weaker in women than in men." This view accords with those of Da Costa, Loomis, Guttmann, and others, so that it may be accepted as a fact that, other things being equal, a loud, low-pitched, harsh voice gives more intense vocal resonance, as a rule, than a high-pitched, or loud, shrill voice.

According to Walshe (*op. cit.*, p. 26) "vocal fremitus and audible vocal resonance bear no uniform relationship to each other, either in health or disease." And yet the conditions enumerated by him as most favorable for the production of both are about the same. They are: 1. A loud, harsh, low-pitched voice. 2. They are both more marked, therefore, in adults than in children, and in males than in females. 3. Both are more marked in the long-bodied and large-chested than in short-chested persons. 4. Chest-walls unencumbered with superfluous fat or extra development of muscle. 5. Both are more intense on the right side than the left.

It is true that vocal resonance may be well marked in a spot where vocal fremitus is feeble or wholly deficient, but it is the exception and not the rule. Indeed, Guttmann (*op. cit.*, p. 128) says that "the intensity of this sound (vocal resonance), at any part, corresponds exactly to that of the vocal thrill (fremitus); the conditions, therefore, on which depend the greater or less audibleness of the voice at any point of the surface of the thorax are precisely those formerly enumerated (*op. cit.*, p. 49) as similarly affecting the intensity of the pectoral (vocal) fremitus."

Both normal vocal fremitus and resonance are most marked in the subclavicular, infrascapular, and interscapular regions of the right side. Over the liver and heart, of course, the normal vocal resonance and fremitus are diminished or even absent, but, according to Walshe, the kidneys, unless enlarged, affect neither.

A curious fact about normal vocal fremitus is that its intensity is slightly increased by the recumbent posture, regardless of the substance reclined on. The voice-sound appears simply to be conducted to the chest-walls with slightly more force in the horizontal position, but the fremitus may be more marked when the person examined reclines on a spring couch, for instance, than a non-vibrating substance.

Of course the vocal resonance and fremitus may be increased or diminished both in health and disease. The conditions most favorable for their production in health have already been given, and the opposite of these will cause the vocal resonance to be more or less diminished, and the fremitus may be entirely absent, as in the case of a woman with a short, fat chest and a high-pitched, soft voice.

In disease, thickened pleura, and also emphysema, will, as a rule, diminish both vocal reasonance and fremitus. The former muffles them according to the degree of thickening, and in the latter case the lungs do not conduct the voice-sounds as well as in health. Stoppage of the bronchial tubes with mucus or the like will also cause them both to be diminished over the part to which

the tubes are distributed. Air or fluid in the pleural sac may cause both to be diminished or absent on the affected side. Occasionally a small spot is found over an extensive serous effusion where fremitus, bronchophony, and bronchial breathing may be obtained. This is probably due to a string of pleuritic adhesion attaching the compressed lung to the chest-wall. The voice and breath-sounds are then telephoned, as Dr. Leaming aptly terms it, along the string of adhesion to the chest-wall. While strings or small spots of pleuritic adhesions may not noticeably affect vocal resonance or fremitus, or may even serve to conduct the voice and breath-sounds with increased force, extensive plastic adhesions and thickened pleura, as a rule, diminish vocal resonance and fremitus according to the degree of thickening. There are, of course, many other causes affecting the vocal resonance and fremitus which space does not allow.

The differentiation of adventitious sounds is usually not difficult, except occasionally, as, for instance, in the case of fine, moist, bronchial and intrapleural râles. According to Flint (*op. cit.*, p. 136) the diagnosis is not difficult; but according to Da Costa ("Medical Diagnosis," p. 247, fifth edit., 1881), "where the secretions are viscid it would require a sense of hearing more delicate than belongs to the majority of mankind to judge, by the application of this test, whether the sound we perceive is formed in the lung or on its covering." Both are heard, usually, more plainly on inspiration than expiration. If they change with coughing, are not uniform, are attended with more or less expectoration and occasional sibilant râles, are bilateral and diffused, or else limited to one apex, they are probably bronchial. If, on the other hand, the râles are unaffected by coughing and are uniform; if the cough be reflex and there is little or no expectoration; if the râles are superficial, dry, and explosive, like the crackling of parchment under the ear, and are found only on one side, circumscribed, and situated about the periphery of the lung, they are probably intrapleural. Owing frequently to peribronchial thickening and commencing induration of lung-tissue, the pitch of the percussion note over both of these râles may be raised in pitch. When it is not, however, it is a point in favor of their being bronchial.

31 West Thirty-third Street, February 17, 1886.

Liberal Studies and the Social Position of the Doctor.—The physician sustains a twofold loss by reason of lack of liberal study. First, a loss in social position. Not the individual, but the average doctor, is here referred to. The social position of the average doctor is not equal to that of the average minister or lawyer, and the reason is largely due to deficiency in education. The remedy for this is in the hands of the medical student. The second loss is in professional practice. This is a consideration of weight to those who are indifferent to the matter of social position. How does liberal study help the physician in his practice? The medical profession has a natural and necessary alliance with all studies of nature and man. This is the reason why the *armamentarium* of the doctor should be liberally furnished. The speaker mentioned a list of some of the studies, not strictly professional, with which a medical student ought to acquaint himself. 1. The languages, especially English and Latin. 2. Natural history, especially botany and zoölogy; also geology and mineralogy. 3. Mathematics. 4. Philosophy. 5. General literature. 6. Rhetoric and Logic.—*Address of Dr. Willard.*

M. Reclus showed, at a recent meeting of the Paris Surgical Society, a female patient who presented a curious lesion. One of her legs was constricted by a congenital fibrous band. Last year M. Reclus removed two-thirds of the band, and subsequently the remaining third. The success resulting has been perfect. [This case evidently belongs to the same class as those in which amputation is produced *in utero* by constricting bands.]—*London Med. Record.*

Progress of Medical Science.

Ptomaines and Leucomaines.—At a meeting of the Paris Academy of Medicine, held on January 12th (*Archives Générales de Médecine*, No. 2, 1886), M. Armand Gautier presented a very important communication upon the alkaloids derived from the bacterial or physiological destruction of the animal tissues. The putrefactive alkaloids, or ptomaines, were discovered by Selmi and the writer, acting independently of each other, in 1870. M. Gautier had remarked that the albuminoid substances became, during the process of putrefaction, more strongly alkaline than was to be accounted for solely by the production of ammonia, and he was thus led to prosecute the researches which led to the discovery of the ptomaines. Selmi had discovered these alkaloids while analyzing the intestinal contents of a man supposed to have died from poisoning. The author reviewed the processes of extraction of these alkaloids and their physiological action, and stated that the marked differences which existed between ptomaines and the poisonous vegetable alkaloids, in their properties and chemical composition, were sufficient to prevent any confusion of the two on analysis. He then discussed the leucomaines, or the physiological alkaloids formed in the tissues during life. The animal organism resists this constant auto-infection by means of two distinct processes: elimination of the poison, and its destruction by oxygen. Most of these alkaloids are very oxidizable, and are rapidly burned up. But when anything occurs to prevent the free access of air to the blood, or to diminish the quantity of hæmoglobin, as in chlorosis, or when hæmatosis is interfered with, the leucomaines accumulate within the organism, and symptoms of poisoning appear.

A Peculiar Deformity of the Foot.—At a recent meeting of the Society of Physicians of Vienna, Herr Billroth presented a patient upon whom an operation for caries of the fifth metatarsal bone had been performed. The diseased portion of the bone was removed by the sharp spoon, and the wound healed kindly, leaving no deformity of the foot. Not long after this the patient, in alighting from a wagon, sprained his ankle, and was in consequence confined to the bed for three weeks. There was, however, no fracture of the bones. But soon the foot was seen to become misshapen, and when presented to the Society the appearance of the limb was like that resulting from a badly set fracture of the tibia. The external malleolus and lower end of the tibia were greatly thickened, and on the dorsum of the foot was an abnormal osseous growth coming down obliquely from the extremity of the tibia. The process was that of arthritis deformans as it is more frequently seen after fractures and dislocations. The case is worthy of note because of its spontaneous origin, and from the fact that the arthritis deformans in this instance, contrary to the generally observed rule, occurred in a tuberculous individual.—*Deutsche Medicinal-Zeitung*, February 4, 1886.

The Treatment of Chorea.—Dr. Joffroy recommends the systematic administration of chloral in combination with the use of the wet pack. To children over ten years of age he gives one drachm of chloral per diem, divided into three doses, after meals; 15 grains are given after breakfast, 15 after dinner, and 30 after supper. In children aged six or seven years, from 30 to 40 grains a day are usually sufficient, but each dose must be large enough to produce sleep in about fifteen minutes after its administration. He has never seen any unpleasant effects caused by the drug other than a roseolous eruption. In very severe cases the writer has the children wrapped in wet cloths at a temperature of 50° to 53° F., for two or three minutes, morning and evening. They are rubbed while in the pack, and are then covered up warmly and kept lying down for half an hour.—*Deutsche Medicinal-Zeitung*, January 21, 1886.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 10, 1886.

THE NATIONAL BOARD OF HEALTH.

THE National Board of Health is largely the creation of the medical profession of the United States, acting through the American Public Health Association. Everything relating to this Board—its work, its difficulties, its progress, and prospects—must be of special interest to medical men. Its membership is largely medical, and among its officers and members we recognize physicians of the highest standing in their sections of the country. Dr. James D. Cabell, the eminent professor of surgery in the University of Virginia, is its President; Dr. Stephen Smith, of New York, long connected with our own board of health, is Vice-President. Other members are: Dr. Robert W. Mitchell, of Memphis, Tenn., who organized and directed all of the work of that city during the great yellow fever epidemics; Dr. Stanford E. Chaillé, of New Orleans, long distinguished as a teacher of hygiene in the University of Louisiana; Dr. Charles Smart, U.S.A., eminent as a chemist and scientist; Dr. James M. Browne, U.S.N., the director of the bureau of hygiene of the Navy. These names give character and reputation to any organization to which they belong, and afford to the profession the highest possible guarantee that the duties of the Board were performed efficiently and honestly. And we may add that, if a Board so constituted does not command the confidence of the profession, the country, and Congress, we despair of ever seeing a central health authority established permanently at the capital. But the Board stands to-day the legally constituted health department of the general Government, fully organized and ready for active service, and yet it is idle at a season when its activity in the field of prevention should be greatest, and for reasons fully set forth in a recent statement by the President of the Board, Professor Cabell. We desire to call the attention of the profession to the facts so clearly and fully set forth in this communication. The appeal is made to every medical man to take such action as will, in his opinion, most certainly rightly influence his representation in Congress. Professor Cabell says the special cause which led to the establishment of the Board "was the great yellow fever epidemic of 1878. A great variety of measures were brought before Congress, designed to organize a health department at the capital, and, after the largest discussion and the most mature deliberation, the law creating the present Board was passed with great unanimity. The law was approved March 3, 1879. It provided for eleven members, seven of whom were appointed by the President and the Senate from different sections of the country, and four were detailed, one each from the Army, Navy, the Marine Hospital Service, and the Department of Justice. This law imposed upon the Board the duty of obtaining information upon all matters affecting the public health, and of advising the several departments of the Government, the executives of the several States, and the Commissioners of the District of Columbia on all questions submitted by them, or whenever in the opinion of the Board such advice may tend to the preservation and improvement of the public health. It also empowered the Board to make, or cause to be made, such special examinations and investigations, at any place or places within the United States, or at foreign ports, as it may deem best, to aid in the execution of the act and promotion of its objects. Immediately on its organization the Board proceeded to institute a series of investigations into matters relating to the public health, and continued them while appropriations were made by Congress for their prosecution. The subjects chosen were those having a national interest, and which could not be thoroughly investigated except by the aid of the Government. During the period that appropriations were made upward of thirty subjects were reported upon, more or less completely. The nature of these investigations will appear from the following among many subjects chosen: 1. A well-selected and fully equipped commission to study yellow fever in Cuba, and the methods of preventing its importation into the United States. 2. An investigation into the prevalence of adulteration of food and drugs. 3. An inquiry into the diseases of food-producing animals in their relation to man. 4. An investigation in regard to the influence of various soils upon sanitation. 5. An investigation upon the flow of sewers in relation to their sizes and gradient. 6. An investigation on the best methods of determining the quantity of organic matter in potable water, and the specific effects of variously contaminated waters upon persons who have used them. We need only say, in regard to these and other works carried forward by the Board, that the results attained are conceded by all to be of great and permanent value to the nation.

The danger of the reappearance of the yellow fever epidemic of 1878 led Congress to enlarge the duties of the Board, and on June 2, 1879, an act was approved which empowered the Board to co-operate with State and local boards in the prevention of the introduction of contagious and infectious diseases into the United States, and their spread from one State into another. By this most important act the combined powers of the municipal, State, and National Governments were for the first time united in one harmonious effort to prevent the introduction of pestilences into this country, and their spread if they secured a foothold. Under this act the National Board added to the efforts of State and local boards all the powers and resources of the general Government toward the suppression of the great epidemic of yellow fever of 1879, and with a degree of success which received universal commendation. It inaugurated and carried on a system of steamboat and railroad sanitary inspections; it made, and as far as it had power enforced, rules securing the best sanitary condition of ships entering the ports of the United States; it established a

series of island refuge stations for infected ships to be cleansed on the South Atlantic and Gulf coasts; it organized and aided in carrying out a system of inspection and vaccination of unprotected immigrants, which prevented an epidemic of small-pox. It also issued a weekly bulletin to health boards and sanitary officers of this country. Unfortunately for the country the law of June 2, 1879, was limited to four years, and expired in 1883. Congress did not re-enact the law, and thus the powers of the Board lapsed in so far as they related to co operation with State and local boards in their efforts to prevent the introduction and spread of epidemic diseases. Nor have appropriations since been made by which the Board could continue the investigations referred to in the act by which it was established. As a consequence, though the Board has been maintained in all its integrity and efficiency, it has been compelled to remain comparatively idle in the presence of epidemics national in their prevalence and disastrous in their effects. It has been our constant and earnest endeavor to establish, on a firm and enduring basis, a branch of the public service devoted to the investigation and elucidation of the great problems relating to the promotion of the health of the people, and to the organization and enforcement of methods of co-operation of the municipal, State, and national authorities in the prevention of the introduction and spread of contagious or infectious diseases. We believe that the question of the need of a public health service in this country is no longer debatable, and that the Board as now provided for by law is the most efficient and acceptable form of organization for the discharge of these important duties. But while we have sought by every proper means and influence to sustain the Board, and thus faithfully discharge the trust committed to our care, we feel that it is for the citizens at large to determine whether, by suitable legislation and adequate appropriations, the National Board of Health shall be invested with such powers as will enable it to discharge properly the duties belonging to such a branch of the public service.

Deeply sensible of the responsibility resting upon us, and impressed with the absolute need of the service contemplated in the law establishing the Board and in the subsequent legislation enlarging its duties, we feel it our duty to lay these facts before them, and to bespeak their earnest co-operation in our effort to preserve and improve the public health. To accomplish this purpose it is absolutely necessary that the matter should be *at once* brought to the attention of the Senators from each State and the Representative in Congress from each district, in order that they may be informed as to the public sentiment in regard to these matters. Without such expression of opinion, legislation at this session of Congress is impossible.

THE USEFULNESS OF SPAYING.

The attempt of the New York Academy of Medicine to check the practice of spaying is evidently an ill-considered one, and is entirely antagonistic to the progressive instincts of the day. The history of the world shows that the practice in question has always been one of the crowning ornaments of the best types of civilization, from the Chaldean to the Roman age. Now that, after many centuries of gloom, it is again brought into beneficent existence, its critics should beware of thoughtless and shallow opposition. The trouble probably lies in the fact that there still lingers an impression among crudely educated minds that the ovaries are organs of social necessity and economic importance. This, however, is a serious mistake. These organs are, it is true, useful for a short period in the existence of a portion of womankind for the perfunctory propagation of the race. Aside from this, however, they are not only of no service, but are a source of racial, domestic, and individual distresses of the greatest magnitude. Philosophers of the present day have ascertained several facts which place this view upon a solid and impregnable basis. No woman wants more than two children, many only one, and a large per cent., including all the unmarried, not any at all. But in fact the population is increasing at a seriously rapid rate, and the modern economist has had to revive and re-adopt the views of Malthus. In this exigency, when society's needs are antagonized by infant multiplicity, the laparotomist steps in, as a kind of modern saviour from the threatened polypædic catastrophe. The woman has her child, the ovary swells, the learned touch of the gynecologist detects a pyosalpinx, and in a twinkling out comes all the source of woman's labors and man's unsought paternities. The laparotomist is plainly society's best friend. Like all benefactors of the race, he must endure opposition and calumny for a time; but his noble work of radically removing the sources of over-population will go on, and we calculate that, at the present rate of increase, in fifty years some thirty-five per cent. of women will be permanently relieved of all the worry of maternal anticipation.

THE WORK OF THE NEW YORK MEDICAL MISSIONARY SOCIETY.

We have received a courteous letter from Dr. George D. Dowkontt, of this city, Medical Superintendent of the New York Medical Missionary "Home and Institute," regarding the subject of "specially trained medical missionaries," to which we referred in our issue of March 6th. Dr. Dowkontt pleads the cause of the specially educated medical missionary. The great need of medical and surgical aid in heathen lands, and the great missionary value of such aid, are referred to, while the scarcity of men both willing and fitted to go is insisted upon. It was for these reasons that the Edinburgh Medical Missionary Society was founded in 1841, and the New York Medical Missionary Society in 1881. The peculiar need for the existence of the latter society, we are told, lies in the fact that medical missionaries must be particularly well educated medically, and American medical colleges are not good enough, and do not furnish sufficient training. Our correspondent adds:

"Allow me to say, in conclusion, that there is great force in the suggestion you made, that we could well spare two thousand out of the four thousand physicians annually graduated in America; and this is forcibly shown in the fact that while in 1880 there was one doctor to 585 people in the United States, there was only one *medical missionary* to nearly ten *millions* of the *heathen*.

"You observe that these could well be spared to go

forth and *disseminate the gospel.* Would to God they were *able* and *willing* so to do, then we need not exist; but they must first possess this gospel in their own hearts and lives to be able to disseminate it, and they must further be actuated by the spirit of self-denial which characterized the Great Physician for body and soul, the Lord Jesus Christ, before they will be *willing* to do so.

"Thank God for the noble men of our profession who have gone forth to heathen lands, as Scudder to India, Parker to China, Livingstone to Africa, and Post to Syria, but oh! for more such men who are willing rather to live to *give*, than to get.

"At the same time, I would not overlook the good work done by Christian physicians at home, work seldom recognized at its full worth, such as our late President, Dr. Alfred C. Post, and others."

THE HEALTHIEST CITIES IN THE WORLD.

JUDGED by their death-rate (in February), the healthiest cities in the word are St. Paul and Minneapolis (*Northwestern Lancet*). The death-rate per 1,000 on the basis of the February rate is 9.60 and 9.88, respectively. We dislike to dethrone the twin metropolis of the great Northwest from its hygienic supremacy, but it does seem very probable that the figures which the *Lancet* bases its statements upon are not strictly accurate. According to them, there were 97 deaths and 220 births in February, a ratio of deaths to births which is beyond all precedent. This ratio in Brooklyn, for example, is as 137 to 125, and in New York as 340 to 289.

The average birth-rate is about 38 per 1,000, while in St. Paul it is only 21.9 per 1,000, and at Minneapolis it is only 15.5 per 1,000. Procreative vigor in Minneapolis, therefore, by the same figures, reaches its lowest ebb. If the statistics are right, then the great salubrity is at the cost of alarming sexual decay.

LOCAL ANÆSTHESIA.

SINCE the discovery of the remarkable effects of cocaine the progress in the study of local anæsthesia has been as wonderful as it has been gratifying. Ophthalmology, to which its employment was at first restricted, soon proved itself too narrow a field, and the journals soon teemed with reports of its use on almost every portion of the body. Nor were the trials confined to the smaller operations. Resections, ligatures of arteries, and amputations followed in the train, with results now so well known. Cocaine, of course, has its limit of adaptability. Although it can never absolutely take the place of ether, its ultimate possibilities are not yet demonstrated. No one has studied the latter with better results than has our esteemed townsman, Dr. J. L. Corning, and we are pleased to notice that his methods of procedure are being indorsed by surgeons all over the country. The trouble with cocaine, when injected, has been the evanescent character of its effect, a matter of serious import in prolonged and severely painful operations. Corning has seemingly compassed these difficulties by confining the circulation of the part by ligature. In his recent work on this subject * are detailed many interesting suggestions bearing on the general question of local anæsthesia, not the least of which is that referring to the employment of his method in sciatica and other neuralgias. There is no doubt that cocaine deserves to be studied from these practical standpoints, and we shall await the results with interest. Dr. Corning is evidently on the right track, and it must be a source of gratification to him to know that the results of his patient labors are being recognized.

* Corning on Local Anæsthesia. New York: D. Appleton & Co.

ARSENIC IN WALL-PAPER.

THE annual excitement in the city of Boston relating to the presence of arsenic in wall-paper has on this occasion, resulted in thorough investigation by a committee of the Massachusetts Legislature, so that the medical profession and the public at large have at length the plain facts before them.

One of the questions investigated was the manner in which the poison was communicated, supposing arsenic to be present in the wall-paper in any quantity. Of course, there are two ways in which this could happen: first by *attrition* or friction, where the color containing the arsenic is rubbed off. This would most probably occur in a bedroom where the bed was placed next to a wall, as the movement of the bedclothes against the wall would produce such an effect. It is obvious, however, that only a very small percentage of the arsenic on the walls could be removed within a certain amount of time, and unless the walls were literally covered with arsenic it would be difficult for a person during the night to collect sufficient of the poison to produce toxic symptoms.

The case, however, assumes very different proportions if the arsenic present could be shown to be decomposed and mixed with the air of the room in the form of a gas. A very small proportion of arsenic breathed as arsenurated hydrogen would cause immediate sickness. It is therefore clear that this form of arsenical poisoning is to be most dreaded.

The Legislative committee tried to clear up this point, whether arsenic could, or could not, be converted into arsenurated hydrogen gas in a room by damp or any other cause.

The evidence of Professor C. F. Chandler, of New York, before the committee, was very convincing as showing that this danger did not exist. It appears that some time ago, as a mere scientific experiment at Columbia College, he tested this matter in the most severe manner. He prepared a large box to represent a room, and hung the interior with a wall-paper full of Paris green. The paper was hung in deep folds dropping from top to bottom of the box, new paste was added to represent the actual conditions and afford the necessary dampness to produce the gas. Air was forced through the box for some time and collected, and afterward analyzed. On all occasions not a trace of arsenurated hydrogen could be found. On the strength of these and other tests, Professor Chandler gave his opinion, that under no conditions could arsenical poisoning occur through breathing arsenurated hydrogen from wall-paper, leaving the only risk that could happen to be from friction alone.

As to the question of arsenic in wall-paper, it was admitted that there was a time when it was used without

limit as a coloring material, but three years ago it was practically abandoned; since this time arsenic has undoubtedly been present in small quantities, even when the color has been sold and guaranteed to be non-arsenical. This may have arisen from the presence of arsenic in the zinc, or other ingredients, of the color, as a simple impurity. But for all practical purposes it may be stated that the use of arsenical colors has been abandoned by reputable manufacturers.

The bill before the Massachusetts Legislature proposes to place a limit to the presence of arsenic in wall-paper at one-fourteenth of a grain to the square yard, which is about half a grain to the piece of eight yards. Since the opening of the investigation it has been found that arsenic is present in large quantities in the paper of fancy boxes, paper for wrapping candy, gentlemen's underwear, carpets, ladies' dresses, and a variety of other articles of general commerce. It is now proposed very justly to make this anti-arsenic bill apply to manufacturers generally.

As to the question of legislating on this subject, Professor Chandler said that one grain to the square yard would be a safe limit, but he was opposed to any restrictive measure, because he thought the danger had passed and did not at the present time exist. Such a bill would cause unnecessary alarm in the public mind, and create a prejudice; it would also cause trouble to the manufacturers, leading to endless litigation and disputes. If, however, any restrictive bill of this kind is passed by the Massachusetts Legislature, it should certainly apply to all kinds of manufactures, particularly to clothing, and articles coming in contact with food-products.

THE DUALITY OF THE TEMPERATURE SENSE.

As cold is but a negative expression, denoting the abstraction of caloric, the idea of distinct sets of nerves, and of separate centres for the perception of heat, and of the absence of heat, is somewhat perplexing. Yet we know that the sensation of pain, which seems to be but an exaggeration of that of touch, may be abolished while the latter is preserved, and conversely, a part may be acutely sensitive to painful impressions, although tactile sensibility has been abolished. And it is now believed that these sensations of touch and of pain are carried by separate nervous tracts to different points of the central system. We know that heat and cold, subjectively considered, are only relative terms, and that an object of a given temperature which feels cold or warm to one person may even convey the opposite impression to another, or to the same person at another time. In myelitis it sometimes happens that the application of ice causes a burning sensation, just as in certain hyperæsthetic conditions the slightest touch causes unbearable pain. These facts and others exemplifying the difference between physical and physiological heat and cold can be explained more easily by the assumption of a dual sense than by any hypothesis which has been hitherto suggested.

In the *Centralblatt für Nervenheilkunde*, No. 20, 1885, Dr. A. Herzen argues with some force upon the existence of separate perceptive centres for heat and cold. His conclusions, formed as a result of experimental and pathological observations, are that there are distinct peripheral organs for the perception of heat and of cold, and that, consequently, the centripetal nervous filaments are also separate; there are, therefore, specific nerves for these two sensations, which, though they have a common course and a common termination, are by no means identical. The sense of cold, he believes, is in some way connected with that of touch, while the impressionability to heat and pain are similarly allied. These sensations are not one and the same, however, and we cannot argue from a loss of the sensation of cold that tactile sensibility is also destroyed, nor conversely.

In the *Memorabilien*, vol. xxx., No. 8, Dr. Friedreich Betz reports a case which adds considerable weight to Herzen's theory. The patient, a man seventy-five years of age, was suddenly seized with a paresis of the left arm. The case seemed at first to present nothing of special interest, until the patient received a severe burn on the hand without feeling any pain therefrom. This led to further examination, when it was found that the sense of heat-perception was entirely lost. As light pricking sensation and an involuntary reflex movement of the arm were the only signs by which he was able to tell that any substance was hot. But the sense of cold-perception was even exaggerated, so much so that rain-drops falling on the hand caused a feeling of almost unbearable cold. In the course of time a slight improvement took place in both muscular power and in the ability to feel the heat of objects, but a perfect recovery was never obtained.

In studying this subject, it is interesting to recall the experiment of Horvath, who found that the application to the skin of alcohol at a temperature of −5° F. abolished the sense of pain-perception, while tactile sensibility was seemingly unimpaired. Were the sense of touch and of cold-perception so slowly allied, one would suppose that the exhaustion of the latter by overstimulation would depress the tactile sense rather than abolish that of pain.

THE MOVEMENT CURE IN CHINA.

It has been generally supposed that the system of kinesitherapeutics, known as the Swedish movement cure, or Lingism, was an invention of Mr. Ling, of the Royal Academy of Sweden, but this is a manifest error. We never had anything against Mr. Ling, but, on the contrary, have always revered his memory, and have gazed upon the machines used to impress motion upon the various parts of the human frame with a feeling akin to awe, such as must have filled the breast of the untutored savage of the plains when first he beheld a locomotive. But candor compels us to proclaim to the world that the Swede was preceded by a Chinaman who invented a similar therapeutic system some four thousand years ago. We have been forced to admit the prior claims of the Chinese to the invention of gunpowder and the art of printing, and now we must yield them the palm also in this other discovery so useful to man and to the cause of civilization.

Dr. D. J. Macgowan has recently published a little brochure, entitled "The Movement Cure in China," in which he gives a brief history of the system, and describes the methods in use at the present day. That the method is one of undeniable efficacy, is proven by the fact that Ch'ee Sung Asz, one of its earliest professors,

had, according to reliable Chinese authorities, already attained the somewhat venerable age of twelve centuries, when he was consulted by the Yellow Emperor concerning the art of prolonging life. Hoang-ti does not, however, seem to have profited by his instructions as much as he might, for he reigned only a hundred years, and then died like the patient of any ordinary physician. One of the greatest authorities in kinesipathy was Ta-mo, or Thomas, a Buddhist patriarch, who came from India in the fifth century of the Christian era. His disciples became celebrated for their athletic and militant proclivities, though the master himself, like some members of his profession in modern times, did not practise what he preached, for he passed the last nine years of his existence in the not very active occupation of gazing at a blank wall, and neglected entirely his life-prolonging exercises.

The latest addition to the literature of the Chinese movement cure is a work by P'an Wei, the Governor of Hupeh, entitled "Important Life-maintaining Methods," published in 1858. In this treatise most minute directions are given for the proper performance of the exercises, and the text is supplemented by numerous graphic and highly artistic illustrations. We can mention only a few of the exercises here, and those who desire to perfect themselves in the art are respectfully referred to Governor P'an's original work in Chinese. While going through the motions the patient is to think about nothing, but should have the mind in a state of absolute quiescence. The neck is to be held with the hands, and the head must then be turned thirty-six times; then press the temples with the index finger twenty-seven times, shut the teeth firmly thirty-six times, swing the arm in its socket twenty-four times, and get on all-fours thirteen times, raising and depressing the back. The patient must then walk one hundred steps, rubbing the abdomen with both hands, concentrating the mind on the "little stomach" in the pubic region, and finally hold the scrotum with one hand, and the belly with the other, changing hands eighty-one times. This very brief abstract will suffice to demonstrate the excellence of the method, and prove beyond question its superiority to the modern system of Ling. If our remarks shall have the effect of leading others to introduce the new-old cure of the Chinese into modern therapeutics, we shall feel that we have had our reward.

MEDICAL WONDERS OF THE WEST.

A RECENT number of a Western contemporary which has fallen into our hands convinces us that in the field of therapeutics the world follows the theory of the Rev. Jasper, and "do move." In fact, as we look over the pages of this periodical we feel that our Eastern therapeutics are sadly behind the times. A few illustrations of Western progress may be in order.

To cure tape-worm, the sovereign remedy is a full tablespoonful of gunpowder, followed in ten hours by a dose of castor-oil. The mode of action is not given. The powder may go off and the parasite be shattered—blasted out, as it were—or it may be simply stunned by the concussion and swept out by the relentless oleum ric. before it has recovered from the shock. The writer of the article further tells us that he or she (for the name suggests one of the fair sex) has "added shekels to my (his or her) bank account, and a little 'good report' to the professional side of the scale as a successful practitioner, and especially for good luck in the treatment of Bright's disease." Main reliance is placed upon an infusion of orange seeds, alternated with oil of turpentine. The former is believed to have a specific action over the vaso-motor centres and to equalize the "venal" circulation. As an "adjunctive" the tincture of lycop. vir., hydrarg. ar., and liatris spic., are given, with the directions that a teaspoonful be taken every six hours until cured. In accordance with our present ideas as to the prognosis in Bright's, it must be necessary to place a bottle of the liatris spic. in the coffin of the patient, so that the dosage can go on according to the above directions.

For scabies the following ointment is recommended: "Acid nit. (stronger) 2 ounces; mercury, 1 ounce; adeps, ½ pound." The writer frankly admits that he has known "one or two persons to be paralyzed by using too copiously." This affliction of the patient, instead of the parasite, is truly a disagreeable circumstance.

The localization of the centres for conscious activity is evidently still *sub judice*. An account is given of a man who was "felling a tree, and it lodged; when attempting to dislodge the tree it fell and struck him about the pubis, knocking him senseless." There is in this sad recital a suggestive hint for our neurologists.

A very interesting discussion ensues as to whether negroes are ever killed by lightning. It seems that out there lightning, as a therapeutic agent, has a sort of selective affinity, somewhat analagous to the effects of belladonna on the eye and aloes on the large intestine. A sort of collective investigation seems to have been undertaken on this topic. One gentleman reports a case in which the subtle fluid attacked first a tree and next a house—joyfully pranced down on one of the rafters, and ended up by performing the happy despatch of an unoffending colored woman, of three. Another observer has records of an occurrence where "a single stroke of lightning sent the souls of two old darkies from 'Dixie's' cotton fields to the land beyond." This writer adds the comment that "a negro's cuticle is pretty hard to penetrate, but when Jupiter Tonans sends his thunderbolt against it a surrender generally takes place." We presume that a temporary armistice is concluded between the combatants.

We might quote further, but we desist. In view of the foregoing facts we almost feel that our own discussion of medical topics is provincial. Still, we shall not prescribe gunpowder or believe in the immunity of our colored brethren from lightning without further evidence.

PROPITIATING THE GODDESS OF CHOLERA.—During the late Dusserah festival at Bombay, it has been discovered that three buffaloes were sacrificed in a most brutal manner with the view of propitiating the Goddess of Cholera. The buffaloes, after being decked with garlands and led around the bazaar, were literally hacked to pieces, while the police and civil authorities remained in convenient ignorance of what was being done.

A NEW MEDICAL SOCIETY FOR ST. LOUIS is announced to be in process of organization.

News of the Week.

A Good Bill.—The Record has on several occasions drawn attention to the bill "For the Better Preservation of the Health of Children in Institutions," introduced in the Assembly by Judge Batcheller, of Saratoga. This bill was prepared by the committee appointed by the New York Academy of Medicine in June last, and if its passage in the Legislature is secured will do much toward lessening the scourge of ophthalmia, which exists so extensively in the orphan asylums of this city and State. Fortunately for the friends of the bill, Judge Batcheller, from a long residence in Egypt, knows much of the ravages the disease has there caused. The Assembly Committee of Public Health, under the efficient chairmanship of Dr. Herman Craft, has favorably and unanimously reported the bill, and it has been passed by the Senate.

Dr. John S. Billings, of Washington, has been chosen to deliver the address in medicine before the next meeting of the British Medical Association, in place of Dr. Austin Flint, deceased. No better man could have been selected to represent American medicine on such an occasion. It is an honor well deserved, and we congratulate Dr. Billings accordingly.

Mr. Lawson Tait on Methods of Diagnosing.—Mr. Lawson Tait, of Birmingham, England, sends the following note: "It has been pointed out to me by more than one correspondent that the expression I used in referring to the method of examining a patient lying on her back has given offence to some of my professional brethren on your side of the Atlantic who habitually employ it. I desire to say that I deeply regret this, and that I desire to express my regret for having used a word certainly much stronger than I need have used when I said that the method was a brutal one. I should be glad if you would permit me formally to withdraw that word, and to say that it was used without sufficient thought to convey the full sense of its offensiveness to me. What I did mean was that I feel it is by no means as delicate a method of examination as that which I habitually employ myself, and more than this I ought not to have said. I certainly am perfectly satisfied, despite what my friend Dr. Mundé said, that our English method is sufficient for nearly every purpose, and that being simpler and more delicate in its application is that which ought to be usually employed."

Dr. James J. Delany died of pleuro-pneumonia, April 2, 1886. He was a native of Waterbury, Ct. He graduated from the College of Physicians and Surgeons, New York, in 1874, and entered the service of Charity Hospital, from which he was called in 1875 to take charge of the small-pox and fever hospitals under the care of the Health Department. While there he carried on a most thorough series of investigations on the use of the cold-pack in fevers, but unfortunately the book containing the records was lost. After five years' service he went to Buenos Ayres, but was dissatisfied with the appearance of the country and returned to this city. He was visiting physician to the Hospital for Nervous Diseases on Blackwell's Island. Dr. Delany was much loved by his professional friends, and the esteem in which he was held by the community was manifested by a large congregation at the funeral services. He was unmarried.

St. Louis Medical Society.—At their last meeting the St. Louis Medical Society adopted the following resolution: *Resolved*, That all reputable medical journals be invited to make such report of the proceedings of this society as they may desire.

Dr. Henry B. Millard, of this city, has been chosen by the president of the International Congress of Hydrology and Climatology to be the American delegate to said Congress. The latter meets at Bayreuth, Bavaria, in October next.

The Mississippi State Medical Association will convene at Jackson, April 21st.

The State Medical Society of Michigan.—The eleventh annual session will be held in Helena, on Wednesday and Thursday, April 28th and 29th, commencing on Wednesday at 10 A.M.

The Death of Dr. Thomas Spencer Cobbold, the distinguished helminthologist, is announced.

The Medical Society of North Carolina meets at Newbern on May 19th.

We fear that our usually-alert contemporary, *The Medical and Surgical Reporter*, does not read his exchanges. It says: "The Association has, we maintain, the right to do just exactly that which it chooses; and when it has announced its decision, it then becomes the plain duty of all right-meaning medical men to uncomplainingly abide by this decision. The claim that the Association has not the right of arbitration has been, we say, clearly abandoned by those who at first made this claim, as is evidenced by their determination to refer the matter in dispute to the Association for arbitration." Turning now to *The American Practitioner and News*, one of the journals which first made this claim, we read: "The new committee pledged the Association to accept the work of the Committee on Organization. It gave the latter full power to create or destroy, to do or undo, according to what it believed would inure most to the interests of the Congress. It promised that its acts should neither be altered, nor revised, nor interfered with, in any manner whatever. It is true that such a pledge was an unusual one to give, and such a promise an unusual one to make, but both were incorporated in the bond executed by the legal representatives and accredited agents of the Association, and nothing remains for that body, when it meets in St. Louis, but to ratify the contract. This it is in honor clearly bound to do. It has absolutely no choice in the matter."

The Decrease of General Paralysis and Increase of Climacteric Insanity in Edinburgh.—Dr. Clouston finds from a study of admissions into the Edinburgh Asylum during the past twelve years that there has been a decrease in the percentage of general paralytics from 7.3 in 1873–77 to 4.5 in 1881–85. He thinks that this indicates a decrease in preventable insanity. He finds an increase of cases of what he terms mental break-down in persons of about the age of sixty who have worked hard. It is, he thinks, a kind of climacteric insanity in the male.

Only a Cold.—The *Lancet* minimizes the illness of the Princess, declaring she is only under the influence of "a common cold." "Only a cold," was the reply of a patient to a query from Abernethy. "Only a cold!" repeated the great medico; "what the devil would you have, the plague?"

Prescribing Fornication.—An eminent Cincinnati evangelist recently said: "The doctors of this country have said to many a young man, 'You can't be virtuous and be healthy.' Is there a doctor here that ever said that to a young man? If there is I want to look him in the face and tell him, 'You are a liar of the deepest dye.' My daughter, your daughter, has the same constitution as your boy, and I dare you by all the power in the Bible to walk up to my daughter and tell her she cannot be virtuous and be healthy! What does the doctor say to you old married men? Does he tell you that you can't be virtuous and be healthy?" To this the *Lancet and Clinic* indignantly replies that "the doctors of this country do not give any such advice as the evangelist asserts." We trust and believe that the great majority do not, but we fear that a small minority do; and we venture to say that the importation of European morals, along with European science and pseudo-science, has had something to do with it. In a blind scientific study of the "case," the doctor may forget sometimes that he owes a duty to society as well as to his patient.

The Lady Doctors.—The Scottish Colleges of Physicians and Surgeons (of Edinburgh and Glasgow) have just decided to throw open to women their conjoint examinations and "triple qualification" in medicine, surgery, and midwifery. Nine of the nineteen licensing bodies in Great Britain are now open to female medical students.

The Memphis Hospital Medical College graduated a class of thirty-seven at its annual commencement, February 26th.

The Omaha Medical College celebrated its fifth annual commencement on March 25th, and graduated a class of five.

The Sunny Side.—Dr. R. C. Moore, of Omaha, Neb., in an address before the graduating class of the local medical college, said: "After an experience of over two-score years, I can tell you honestly and candidly that there is but little truth in all of these doleful prognostications of these dyspeptic doctors. The skilled and conscientious physician is the happiest, most self-satisfied, and best-fed man in the community. If he attends to his business, if he be honest in his dealings with his fellowmen, if he be endowed by nature with common sense, and has acquired by study the fundamental principles of his profession, he cannot only enjoy the social pleasures of cultivated society, but he can accumulate a sufficiency of this world's goods to render his declining years free from pecuniary embarrassment, without arduous labor at the time of life when the desires of man are for freedom from business perplexities and physical fatigue."

American Surgical Association.—The annual meeting of the American Surgical Association will be held in Washington, April 28th, 29th, 30th, and May 1st.

Mutual Protection against Blackmail.—We learn from Dr. E. J. Doering that a physicians' protective association is to be organized in Chicago. It is stated incidentally that during the month of March four suits for alleged malpractice have been brought in Cook County against well-known physicians.

The Cost of Sickness in the hospitals of France in 1880 was $10,779,235.

Gonorrhœa in the Family.—M. P. Aubert contributes some facts to the *Lyon Médical* which show that gonorrhœa introduced into a family by the erring husband may affect not only the wife, but children. Mme. X—— sent to him her little daughter, aged four, suffering from "whites," and Dr. Aubert found that she had gonorrhœa, with numerous gonococci in the secretions. The mother had herself suffered from excessive leucorrhœal discharge for several days, and she stated that her husband had had a discharge for some weeks. The family attributed it all, says Dr. Aubert, to some bad wine which had been used. In a second instance, father, mother, and little girl all had the gonorrhœa. Here it was established that the mother, while suffering from the discharge, twice took her daughter into the bath with her. It was thought that the contagion came in this way.

New York Neurological Society.—At the annual meeting of this society, April 6th, Dr. C. L. Dana was elected president, Dr. George W. Jacoby secretary.

Misfortune to the Graduates of the Jefferson Medical College.—After the college commencement, which was held on April 2d, the Faculty gave a banquet to the newly-made doctors at Natatorium Hall. A temporary floor had been placed over the basin fixed for swimming in the west end of the room. On the temporary floor stood a piano, around which a number of the doctors were standing. Suddenly the floor gave way, and about twenty-five of the party fell with the piano and the débris to the bottom of the basin, a distance of twenty feet. Three persons were seriously hurt, but there was no fatal injury.

The Contagious Diseases Acts of Great Britain, by which prostitution was regulated in garrison towns, have been repealed by a vote of 245 to 131. English medical opinion, as a rule, supported the acts, and *The Lancet* announces gloomily that henceforth "disease and immorality in their most revolting forms are to riot in the midst of our garrison towns." The sentiment of the English public, however, was against the acts.

The Philadelphia Polyclinic and College for Graduates in Medicine has established a hospital for operative and other cases at the college building, Broad and Lombard Streets, Philadelphia. A number of ward patients have already been treated in the new hospital.

A National Sanitary Convention is announced to be held in Philadelphia, under the auspices of the Pennsylvania State Board of Health, on May 12, 13, and 14, 1886.

An Independent Health Board for Massachusetts.—The bill separating the Massachusetts State Board of Health from that of lunacy and charity has become a law.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 1, 1886.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT announced as memorialist for S. Oakley Vander Poel, M.D., LL.D., Albert Vander Veer, M.D., of Albany.

Reports from Sections were made, containing brief abstracts of their proceedings.

DR. HENRY C. COE then read a paper entitled:

IS DISEASE OF THE UTERINE APPENDAGES AS FREQUENT AS IT HAS BEEN REPRESENTED?

in which the author said that this title did not imply skepticism so much as it did a mildly negative answer to the question. Not only was our knowledge of the normal ovary in an unsettled condition, but especially crude was, as far as text-books were concerned, our knowledge of the pathological conditions supposed to be included in such terms as ovaritis, periovaritis, etc. But interest in ovarian disease would not die out in this country, at least, if the work of the surgeon with its rapid growth was able to keep it alive. The aid of the microscope was only rarely invoked by gynecologists, and not infrequently ovaries were removed and passed into the hands of the pathologist with the request that the diagnosis be sustained, when the subsequent examination made it extremely difficult to justify the wisdom of the operation.

The question, then, naturally arose, What is a normal ovary? So much had been said about the common occurrences of chronic ovaritis, cystic degeneration, etc., that, if true, the existence of a normal ovary, except in animals, might well be doubted. Besides, the minute structure of the ovary was not constant, histologically. Under these circumstances it could be readily seen how difficult it was to determine where the physiological condition ended and the pathological began.

Ovaries had been removed because they were regarded as cystic, and yet it had not been decided what was meant by a cyst; that is, when the ovisac ceased to be a vesicle and became a cyst.

The ovary ordinarily encountered was not the typical one illustrated in the text-books on histology, to be sure, but it was not to be regarded, on that account, as an organ suitable to be plucked out.

Then the question arose, To what extent may an ovary deviate from the so-called typical without being diseased? In general, the conditions which had been said to justify the operation for the removal of ovaries were included under variations in size and shape, the presence of cysts, more or less numerous, upon their exterior, changes affecting the thickness of the cortex and the stroma, adhesions, etc. Dr. Coe then examined the several points, and said that the variations in size and shape might be such as to make them spherical, oblong, or discoid, instead of almond-shaped, and still they might be perfectly normal. Under the influence of simple congestion the organ might be temporarily enlarged. The moderate enlargement due to congestion had been noticed at the operating-table, but it did not necessarily imply disease. Considerable increase, a decided diminution in size, did not positively indicate an abnormality. The ovary was not a stationary organ; it varied in this respect according to age, and also never returned to its natural size after labor. It might be seamed and scarred and changed in color as age increased. Thickening of the cortex might be perfectly natural in an ovary, and frequently existed in an ovary which was in full functional activity. So long as the Graafian vesicles could get to the surface there was not much thickening, and localized cirrhosis in the depths of the stroma were not uncommon. Cystic degeneration was most frequently given as a condition that justified extirpation, and he had rarely heard the diagnosis of cystic degeneration called in question when three or four vesicles, not larger than small peas, had been found upon the exterior of the organ. If all the so-called cystic ovaries were to be regarded with suspicion, there were but few women who were positively out of danger. Ordinary cases of hydrops ovarii seldom acquired any importance clinically.

On the other hand, as had been demonstrated by Olshausen, there was a true cystic degeneration, but it is not common. From all that was known, pathologically, concerning cystic degeneration, it could be said truthfully that, given an ovary slightly above the usual size, with a half-dozen transparent vesicles, as large as peas, upon its surface, and functionally active, we were not justified in inferring that such an ovary was in extensive cystic degeneration, and that, consequently, it should be removed without regard to other and more positive indications. Nor was cirrhosis to be inferred because of the presence of a few spots of fibroid degeneration. If a number of sections showed perfect ovisacs, or Graafian follicles, the deduction could not be made safely that this was evidence of a diseased organ which should be removed. Neither did partial disease imply total loss of function. Schroeder had even gone so far as to remove only the diseased portion of ovaries, and with the expectation that what remained would perform the function of the organ. Although there was room for doubt with regard to the success of this method, it was evidence of the conservative tendency of its author, adn furnished food for thought. With reference to *tubal pathology*, there was no discrepancy of opinion as to removal of tubes distended with pus being justifiable and necessary. But Dr. Coe was not prepared to accept the statement of Mr. Tait that it was illogical to attempt to make a differential diagnosis between certain conditions, and, on the contrary, believed that it was illogical not to attempt to separate the different classes of cases. Against the sweeping statement made by Mr. Tait, that in chronic ovarian disease the tubes were invariably involved, Dr. Coe protested. He then asked what constitutes disease of the tubes? Nothing was plainer than a plain case of pyo-salpinx; but the multiplication of terms which had been seen, and which was increasing, had not been fortunate enough to secure the support of pathological observation. A healthy Fallopian tube was capable of increase in size. He had sought for evidence of catarrh of the tubal mucous membrane, but had not been successful, and the conditions which he had found in the so-called cases of catarrhal salpingitis, were such as he had been unable to distinguish from the normal; that is, moderate hyperæmia of the mucous membrane, which was covered with a thin layer of mucus. Cilia in active motion was proof against the presence of inflammation. Nor had he found that hypertrophy of the muscular coat of the tube, and changes affecting the lumen, except pyo- and hydro-salpinx, were common. The number of cases of pyo-salpinx reported by Dr. Wylie, was a larger proportion than usual, and the same was true of the cases reported by Imlach of Liverpool. During two years Dr. Coe had examined microscopically every specimen which came within his reach, and these included a large proportion of the cases in which the operation had been performed in the city, and he had found that in not more than one-fifth was pyo-salpinx or hydro-salpinx present; that hypertrophy of the muscular coat existed in a less number, and that hæmato-salpinx had been extremely rare. He had come to be skeptical concerning the diagnosis of pyo-salpinx where there was no pus in the tube; no pus, no pyo-salpinx.

With reference to symptoms, they were not due to the condition of the ovaries and tubes so much as to localized peritonitis and to neuralgia, pure and simple; and that these symptoms were removed by extirpation of the uterine appendages he did not believe. It would not be proven that a cure had been effected, until it could be

shown that the patient was well at the end of six years after the operation. The special point upon which he wished to insist was that the presence of insignificant changes in these organs was insufficient to subject a woman to the risks of abdominal section.

Dr. W. T. Lusk said that he was not, by any means, an enemy of the operation commonly known as Tait's, but he had seen it performed when ovaries had been removed which were said to be examples of cystic degeneration, but which in all respects were similar to those he was in the habit of exhibiting as specimens of normal ovaries, when he taught physiology. It seemed to him that since it had been learned that ovaries could be removed with but little risk to the life of the woman, surgeons were under strong temptation to perform the operation much too frequently. He had the suspicion that even Mr. Tait had sometimes removed ovaries and tubes which might have been properly included among the normal. The theory that the abdominal cavity should be opened in doubtful cases was at the bottom of the mischief which the paper of the evening was intended to combat.

Dr. Lusk had some doubt as to whether, in cases of pyo-salpinx, surgeons would long feel obliged to open the abdominal cavity and remove the tubes, in order to effect a cure; and he thought they would learn that it was possible to reach these tubes through the vagina, possibly by means of some such an instrument as that devised by Dr. Mundé, and thus be able to treat these cases successfully in that way.

Dr. W. Gill Wylie did not wish to defend any one for removing normal ovaries and tubes. He might have taken some out in his lifetime, and Dr. Coe ought to know, as he had had opportunity to examine nearly all the specimens he had obtained by operation. He was unable, however, to see how the matter was to be settled if an absolute distinction was to be made between the surgeon and the pathologist.

His own guide, with reference to removing the ovaries and tubes, had been the symptom, aided, of course, by what knowledge he could obtain by physical examination, and in only a very few instances had he been in doubt as to the condition of things that would be found on opening the abdomen.

Now he rarely performs the operation, except for pyo-salpinx, and not then unless the symptoms plainly indicate the operation and the woman wishes to have it performed. He thought that it was not very difficult to diagnosticate pyo-salpinx, but believed that the skill in diagnosis would consist in recognizing cases of pyo-salpinx in which rupture into the peritoneal cavity was liable to occur, and so produce general peritonitis.

When the patient was unable to perform her work, suffered from pain in the side almost constantly, or was bed-ridden, and there was pyo-salpinx, he believed that laparotomy for removal of the uterine appendages was justifiable, and was the proper operation to be performed. He regarded aspiration in such cases as only temporizing.

He believed that localized peritonitis was associated with the disease of the ovaries and the tubes in a very large proportion of cases, and regarded the history of repeated attacks of pelvic peritonitis as the best evidence of disease of the ovaries and tubes.

He especially avoids operating in the hysterical or hystero-epileptic cases, notwithstanding the tubes and ovaries were involved in almost all these cases, whether diseased or not he was not prepared to say.

Dr. W. M. Polk said that the answer to the entire question was that salpingitis was not a new disease; that it had been recognized for years; and that it had been cured over and over again without cutting the bellies of the women open and removing their uterine appendages, and they had afterward had babies. The name under which it had been described in the text-books was cellulitis; that is, there is a mass in the region of the broad ligament, sometimes continuous with the uterus, sometimes not, the uterus is fixed to a greater or less extent, with considerable fever in some cases, or slight in others, etc. On opening the abdomen in *fifteen* cases giving these symptoms he had removed a mass from the posterior surface of the broad ligament, but there was no induration whatever between the layers of this ligament. He wished to emphasize the point that when the masses thus removed were cut open, pus would be found in the tubes. He could not, therefore, help reaching the conclusion that they were talking about a condition which surgeons had recognized for years and had treated successfully, curing the patients.

Again, he had reached the conclusion that the indurations found were the result of extension of inflammation from the interior of the uterus; that if the cases were called peritonitis with salpingitis, a position would be taken that could be maintained; and that in the majority of cases of what are called cellulitis, there has been an ordinary endometritis which has extended to the tubes and to the peritoneal cavity; it may also extend along the line of the blood-vessels or the lymphatics.

He was also prepared to reach the conclusion that at first pelvic abscess was in nearly all cases nothing more than an accumulation of pus in the tube, which went on and involved the pelvic tissues; in a minority of cases the inflammatory process may originate between the layers of the broad ligament.

With all this he believed that there was a minimum number of cases, and these were cases of pyo-salpinx pure and simple, in which laparotomy for removal of the ovaries and the tubes might be performed with propriety, and was a justifiable procedure.

Dr. Paul F. Mundé said that, in 3,000 cases of disease of the female sexual organs he had treated, 117 were recorded as ovaritis and salpingitis, combined with peritonitis, which would sustain what had been said by Dr. Wylie and Dr. Polk. Besides, he had recorded 212 cases of uncomplicated ovaritis. He would therefore say that, according to his experience diseases of the uterine appendages were quite as frequent as generally supposed, although he did not, by any means, mean that cases requiring removal of the ovaries and tubes were so frequent as they might be considered to be by the followers of Mr. Tait. To say that there was something in the pelvis that was not normal, was not difficult; but that was not a diagnosis. With regard to operative interference, the symptoms must be the guide, and if they were such as would not yield to other measures, and the woman wished to have it performed, he regarded laparotomy for removal of the uterine appendages as a justifiable operation. Removal of normal ovaries, he did not approve of. Laparotomy, however, in these cases should not be resorted to rashly. He did not regard pelvic abscess as a pyo-salpinx which had worked its way out, but believed that it began in the cellular tissue.

Dr. E. Noeggerath still adhered to the views which he expressed eleven years ago, that the large majority of peri-uterine affections are of peritonitic origin; but that cases of cellulitis and perimetritis also occurred from other causes there was no doubt, although only under one circumstance, that is, whenever there has been a lesion of the mucous membrane of the uterus, and the lymph-sac of the lining membrane has been opened.

If, however, the inflammation of the lining membrane of the uterus was carried into the peritoneal cavity, and there was no lesion of the mucous membrane of the uterus, it was always by way of the tubes.

With regard to frequency, endometritis, with or without peritonitis and salpingitis, was the most common affection which we had to treat. He had become convinced that it was possible to relieve, by careful and rational treatment, a great many who were operated upon for removal of the uterine appendages. However, in the cases in which Dr. Wylie had operated, the specimen showed that the operation was justifiable in any case.

Dr. Coe said, in closing the discussion, that of course a certain amount of doubt must always attend clinical examinations that did not belong to the diagnosis of the pathologist who had the specimens before him.

The Academy then adjourned.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, March 2, 1886.

Alexander S. Hunter, M.D., Chairman.

Dr. A. H. Goelet read a paper entitled

RAPID DILATATION OF THE CERVIX UTERI FOR DYSMENORRHŒA AND STERILITY,

in which he set forth his views concerning the indications for the operation and the method of performing it. The indications were: First, dysmenorrhœa, constant and severe, where stenosis with obstruction is present; this includes flexion with obstruction. In these cases the pain is relieved by the flow; it sometimes becomes more pronounced after marriage. Second, it is indicated in cases of acute flexion, where the probe can be easily passed after the proper direction of the canal has been ascertained; there is no actual obstruction—the dilatation is done to overcome the flexion. Third, it is indicated where little or no flexion exists, and there is only slight obstruction, the passage of the sound through the internal os is attended by pain, and there is no other cause of the dysmenorrhœa and sterility. Fourth, it is indicated in a class of cases which give a history of no inconvenience, but sterility exists and dysmenorrhœa, at first only slight, gradually increasing in severity; the sound passes without pain until the fundus is reached, and an albuminous fluid exudes from the os. In these cases endometritis did not exist previous to marriage, but the congestion consequent upon that state has lessened the calibre of the uterine canal and increased the secretion from the uterine cavity. Complete dilatation, if maintained, will alone cure some of these cases.

The proper time for performing this operation is a week or ten days after the cessation of the menstrual flow, and much can be done by preparatory treatment to favor a good result.

The mode of performing it consists in anæsthetizing the patient, exposing the cervix through a speculum, introducing a sound, first to ascertain the direction of the canal, fix the cervix, drawing it down slightly, introducing the dilating instrument, which usually goes through the internal os with a *jump*, making it evident that it has entered the uterine cavity, and then applying gentle pressure to the handles of the instrument until they are brought together and the required amount of dilatation has been effected, usually the full extent of the instrument.

If the dilator does not pass the internal os with a moderate amount of pressure, introduce the applicator *repeatedly*, armed with cotton, which will increase the size of the opening so that the instrument can be introduced *without* force. When the handles have been brought together they should be held for a few moments, then removed, and a Hank's dilator introduced, to be followed by the applicator. This done a tampon of boro-glyceride is applied and the patient put to bed. On the following day introduce a stem made of hard rubber, slightly curved, tunnelled, and perforated in the centre, and for a week this is to be removed daily, cleansed, and replaced, when it can be removed permanently, and the patient allowed to get up. Dr. Goelet regards the operation as perfectly safe and effectual, if done properly, and in eighty cases it has not failed in a single instance to cure dysmenorrhœa.

The following conclusions were reached: 1. Rapid dilatation is a perfectly safe and justifiable procedure. 2. If a stem be used in the after-treatment recontraction does not occur. 3. The operation is demanded by the following conditions: First, marked stenosis with or without flexion; second, acute flexion without actual stenosis or obstruction; third, slight stenosis shown by passage of the sound, and dysmenorrhœa and sterility existing without other cause; fourth, moderate endometritis, acquired, with narrowing of the canal and lack of free drainage for the discharge.

Dr. Paul F. Mundé said that he had been particularly interested in the study of rapid dilatation during the last twelve or thirteen years, and he had found that the operation was very satisfactory so far as dysmenorrhœa, depending upon a constricted uterine canal, was concerned. He thought that the cases of dysmenorrhœa in which he had failed to afford relief did not reach ten per cent. The dilatation had been practised either at the dispensary or in his office, and he was not aware that any bad results had followed the operation. He used at first Ellinger's dilator, being the first to bring the instrument to this country, and subsequently substituted Palmer's dilator. He had not been so successful in the use of other forms of dilatation. The relief in a proportion of his cases had been only temporary, and the operation was repeated. In all the cases referred to the dilatation had been performed without the administration of an anæsthetic.

In twenty-nine cases of *sterility* he dilated thoroughly and effectually under the influence of an anæsthetic, using the Palmer dilator in all except five (in these dilatation was accomplished by means of tents), and by repeated dilatation at his office for several months kept the canal open. In all these cases a stem was used, either hard rubber or glass, and the patients were kept in bed for a week or ten days. During the first week the stem was kept in place by means of a tampon, and afterward by the cup-shaped pessary devised by Thomas. On an average, the patients wore the stem for three months.

In only two cases did pregnancy follow, so far as he knew. In one of the cases the dilatation was done with laminaria tents, and in the other with a dilating instrument. Three out of the twenty-nine cases had pelvic cellulitis, due to the operation. He was inclined to believe that more than two got pregnant, but at the same time he believed that impregnation after dilatation was rather exceptional—especially if the woman has been married and sterile for five years—probably not more than twenty-five per cent.

Dr. W. Gill Wylie advocated the use of the dilator for the cure of dysmenorrhœa and sterility, and he also almost always uses it when he wishes to make a uterine application. He thought that sufficient credit, in general, had not been given to Dr. Ball, of Brooklyn, for bringing forward this method of treatment for these two conditions. After Dr. Ball read his paper Dr. Sims always used the dilator after using the knife, and the method had a very great influence on Dr. Sims' results. Dr. Wylie could cite four cases of sterility, in three of which pregnancy took place within one year after the operation was performed. In quite a number of cases Dr. Wylie believed it to be physically impossible to pass these dilators through the internal os at the first sitting. He never attempts the operation as long as the uterus is fixed. Dr. Wylie makes a distinction between dilatation and divulsion. Dilatation will cure four out of five cases of dysmenorrhœa, and the patients can be treated in the office.

In *sterility*, *divulsion* is more commonly practised. Certainly he had obtained much better results, both in dysmenorrhœa and in sterility than Dr. Mundé had reported, yet not all cases had been cured. He also regarded it as important, as did Dr. Sims, not to draw the cervix down with the tenaculum.

Dr. A. M. Jacobus had dilated, according to Wylie's method, in a good many cases, and, so far as dysmenorrhœa was concerned, with very good success. In some cases he knew that pregnancy had followed the opera-

tion, which he had in most cases performed without an anæsthetic. Dr. Jacobus also spoke of the necessity of treating the mucous membrane of the uterus, after dilatation had been accomplished, and believed that by so doing the results would be improved.

Dr. H. Griswold said that he had not been very fortunate in practising extreme dilatation, but had been more successful with repeated moderate dilatations.

Dr. Boldt regarded chronic endometritis as an indication for dilatation, and thought it should be performed in these cases as thoroughly as in flexion or stenosis of the canal. So far as sterility was concerned, his experience was about midway between that related by Dr. Mundé and Dr. Wylie. He had had a few cases in which cellulitis followed the operation. Dilatation should never be performed when there is cellulitis or old pelvic peritonitis.

Dr. J. H. Fruitnight had performed dilatation with almost uniform success; eighty per cent. of the cases having become pregnant. *Divulsion* should be done under an anæsthetic.

Dr. Mundé could not agree with Dr. Wylie that the cervix should not be drawn down with the tenaculum.

The Chairman had found that it was desirable, in the cases best adapted to this method of treatment, to have an instrument which is sharply curved at one-eighth or one-fourth of an inch from its distal extremity, and with such an instrument he had been able to pass the sharpest flexion readily.

Dr. Goelet said that, after all, sterility was a secondary consideration, the pain of dysmenorrhœa being the symptoms from which the patients wished to be relieved. Dr. Goodell had reported nineteen per cent. of cures in sterility. Statistics concerning sterility, however, were necessarily unreliable. He regarded it as somewhat dangerous to divulse to the extent of rupturing the circular fibres of the cervix, and also believed that dilatation could not be performed thoroughly without an anæsthetic. With regard to recontraction, he found that it occurred before he used the stem. He does not expect now that the os will remain as large at the end of a year as it was at the time the patient passed from under treatment, but if the sound passes freely it may be regarded that the patient is cured permanently if the dysmenorrhœa has been relieved. He had always found that in severe chronic endometritis the uterine canal was sufficiently open to admit of treatment without dilatation, and therefore to allow free discharge.

The Section then adjourned.

Epilepsy Caused by the Sight of a Cadaver.—M. Legrande du Saulle reports the following eight cases in which the first attack of epilepsy in children occurred immediately after they had seen a dead body. 1. A child, ten years old, daughter of an hysterical mother, saw her mother's corpse, and was seized with epilepsy, the attacks recurring every day. 2. A girl, six years old, the child of a drunkard, saw her father's body, was greatly terrified, and became epileptic. 3. A child, twelve years old, whose father was a drunkard, the mother hysterical, and whose brother died in convulsions, became epileptic immediately after looking on a cadaver. 4. The fifteen-year-old daughter of an intemperate father, whose uncle was of unsound mind, saw her father's dead body and was seized with epilepsy, and manifested homicidal tendencies. 5. A girl, seven years old, saw her father's corpse and became epileptic, the atttacks recurring at intervals of a week. 6. A young girl, fourteen years old, saw her father die suddenly, was seized with convulsions, and became epileptic. 7. A child, ten years old, began to suffer from nocturnal epilepsy after she had seen the dead body of her grandfather. 8. A young woman, twenty-five years of age, saw and embraced her father's corpse and immediately had an attack of epilepsy, the convulsions recurring about once a month.—*Lo Sperimentale*, December, 1885.

(From our Special Correspondent.)

THE CONJOINT SCHEME AND THE EXAMINATION UNDER IT—WORKS ON NERVOUS DISEASES—CARDIOGRAPHY AND ITS USES—NOTES FROM THE SOCIETIES—QUININE DEPOSITED IN THE EYES—SYMPATHETIC OPHTHALMIA—DOUBLE OPTIC NEURITIS IN CEREBRAL HEMORRHAGE—A NOVEL TREATMENT FOR HERNIA CEREBRI—NERVOUS SEQUELÆ TO VARIOLA—NECROSIS OF LOWER JAW FROM MEDICINAL USE OF PHOSPHORUS—FURNEAUX JORDAN'S AMPUTATION—UNUSUAL PRESSURE-SYMPTOMS FROM A MEDIASTINAL TUMOR—DIFFUSED SYMMETRICAL PULMONARY CIRRHOSIS—ANTE-MORTEM DIGESTION OF STOMACH—THE PURIFICATION OF THE THAMES—THE LUNACY BILL—MR. STANSFELD'S MOTION FOR THE REPEAL OF THE CONTAGIOUS DISEASES ACTS.

London, March 16, 1886.

I have on several occasions referred to the new "Conjoint Examinations," and the ill-repute for fairness they have acquired—the first examination more especially—with both teachers and students. Changes in the first examination have been considered advisable, and the following alterations have been approved by the two colleges, and will no doubt come into force at once: 1. Medical botany to be omitted. 2. The option to be allowed of taking materia medica with either the first or second examination. 3. The area of examination to be more limited both in chemistry and materia medica. The chemical part of the latter is to be transferred to the examination in chemistry. More stress is to be laid on the physiological action of drugs. One alteration which is much needed, but to which the committee do not allude, is a more orderly mode of conducting the examination, so as to prevent such confusion as, I am told, reigned at the October examination. It is also a strange state of things that two great colleges cannot arrange to have the practical examination in chemistry conducted at one centre, instead of sending the candidates in batches here and there all over London. I was informed by a candidate who was examined in practical chemistry at the College of Physicians, that the laboratory improvised there was a veritable cellar, with "a dim religious light," and imperfect standing-room for the numerous candidates. The collection of reagents was in a lot of odd bottles irregularly labelled—some with the formulæ and some with the chemical names—suggesting the idea that, instead of ordering a proper series of reagent bottles from a wholesale chemist, the College had utilized for the purpose the sweepings of a dozen surgeries, possibly presented to it by as many general practitioners on relinquishing general practice to become physicians. Platinum was not to be had for the asking, so the flame-test could not be applied. Such was the account I received from an eye-witness, and, even if it be taken with a grain of salt, it reveals a by no means creditable condition of affairs. Let us hope for better things on the completion of the new Examination Hall, the foundation-stone of which is to be laid by the Queen to-morrow week.

It is often said that this is an age of nervous diseases. It certainly is one in which great attention is paid to them. I lately chronicled the formation of the Neurological Society. A very full "Handbook of Diseases of the Nervous System" has just been published by Dr. James Ross. It follows closely the lines of his enormous monograph on the same subject, and may, in fact, be regarded as the same book "boiled down." As is usual in modern medical monographs, it includes a very elaborate *résumé* of the anatomy, physiology, and general pathology of the subject. The book is being also issued in America; but, instead of being reprinted there from advance proofs, the whole issue has been printed in Philadelphia, and the copies for British use sent over here.

We are also promised a work on the same subject by Dr. Gowers. Dr. Gowers has already written several works on nervous diseases, including two very popular and successful ones on "The Diagnosis of Diseases of the Spinal Cord" and "The Diagnosis of Diseases of the Brain," respectively, the last-named being issued only last summer. The latest announcement is of a treatise entitled "Paralyses: Cerebral, Bulbar, and Spinal," by Dr. Bastian, one of Dr. Gowers' colleagues at University College Hospital. Dr. Bastian is evidently determined not to be behind. His forthcoming treatise will probably be found to be an expansion—brought up to date—of his former excellent little book "On Paralysis from Brain Disease," which appeared in 1875. The student of neurology has also two other recent books to choose from for his reading, viz., Dr. Wilks' Lectures on "Diseases of the Nervous System," and Professor Grainger Stewart's "Introduction to Diseases of the Nervous System."

Cardiography was discussed at some length at Tuesday's meeting of the Medical and Chirurgical Society. Dr. P. M. Chapman read a paper on the subject, in which he endeavored to show (from numerous observations by himself and others) that in the human subject the duration of the systole diminishes by a constant quantity as the pulse frequency increases. This constant diminution he made out to be .0085 seconds for every increase in frequency of five beats in the minute between the rates of forty-five and one hundred and fifty per minute. He pointed out the importance of this rapid diminution in duration of systole as providing the heart with more rest, and remarked that a high pulse frequency was not necessarily attended with rapid cardiac failure.

Dr. Broadbent believed the relative duration of systole and diastole could be gauged by the stethoscope. He considered blood-pressure had a great deal to do with the diminution of the duration of systole. In fevers this diminution was due to diminished resistance in the peripheral circulation, though in some, *e.g.*, scarlatina, the arteries were not relaxed, and no diminution occurred. The normal rhythm might be lost and auscultation reveal the complete "tic-tac." The diastole might be actually shorter than the systole. Similar phenomena were met with in acute renal disease, in which a slight elevation of temperature was accompanied by considerable increase in the peripheral resistance. In some cases of acute albuminuria the heart rhythm varied almost from day to day; here cardiac exhaustion played a part. He had also observed the lengthening of systole gradually diminish as the heart gained power. He believed that, controlled by careful stethoscopic examination, cardiographic tracings were of considerable value.

Dr. Sansom also spoke in favor of the cardiograph, and maintained that it could distinguish for us between mitral stenosis and aortic regurgitation accompanied by a thrill.

Dr. Angel Money rather threw cold water on the previous speakers by remarking that he had taken five hundred cardiograms, and had found them of little value.

LONDON, March 15, 1886.

No one can complain of there having been any lack of subjects for discussion at the society meetings within the last week or so. Such a variety of topics have been discussed and so many cases of interest brought forward that I can only give a few brief jottings about some of the most important items in the proceedings.

At the last meeting of the Ophthalmological Society, Mr. Lang showed a patient in whom a deposit of quinine (which had been given medicinally) had occurred in both eyes, without impairment of vision.

Mr. Nettleship read the report of the Committee on Sympathetic Ophthalmia. The report was based upon an analysis of two hundred cases. The conclusions at which the committee arrived were as follows: Removal of the exciting eye, whilst it had not been proved to have any marked effect on the progress of the sympathetic disease, certainly did not increase the severity of it. Comparing equal numbers of cases in which (soon after sympathetic inflammation) the exciting eye was, and was not, removed, the sympathetic inflammation was more fatal to sight when the exciting eye had *not* been removed. This argument for early excision, however, was somewhat weakened by the fact that the excess of recoveries after early excision was partly due to the natural mildness of the disease in those cases, and the excess of losses in the other cases to their greater natural severity. The committee considered that mercury had little or no effect. They thought early iridectomy (on the sympathizing eye) was less unfavorable than usually supposed. In a few cases it had been performed on the exciting eye, and in nearly all with benefit to both eyes. They considered sympathetic ophthalmia to be extremely rare without perforation of the exciting eye having occurred. With reference to the interval between the lesion of one eye and the sympathetic inflammation in the other, only a dozen cases were found in which it was more than a year, and only eighteen in which it was a month or less. When the disease occurred late there seemed a greater probability of blindness ensuing.

Dr. Bristowe read the notes of a case of cerebral hemorrhage in which double optic neuritis occurred. The case was diagnosed during life as one of cerebral tumor. There was conjugate deviation of the head and eyes which persisted for five or six weeks. There was paralysis on the right side of the body. At the autopsy a large cavity was found in the left optic thalamus containing partly decolorized clot. The posterior limb of the internal capsule was ruptured, and both the lenticular nucleus and the white matter of the temporo-sphenoidal lobe damaged. Dr. Hughlings Jackson concurred with Dr. Bristowe as to the extreme rarity of the association of optic neuritis with simple cerebral hemorrhage. Hemorrhage from a tumor might lead to error. A large clot, on the other hand, might be regarded as a foreign body.

At last week's meeting of the Clinical Society, Dr. Maclaren recounted a case of hernia cerebri which he had successfully treated by pressure applied within the skull. The case was originally one of compound fracture and hernia cerebri supervened. The protrusion was shaved off, and then a silver plate placed on the mass within the skull so as to block the opening, the plate being a little larger than the aperture. This had no ill effects, though the plate slipped once, reproducing the hernia cerebri. The protruding mass was again excised and the plate readjusted, this time the edges of the scalp being brought into apposition and sutured over the plate. The latter was left in place for two months when it was removed and, the protrusion of brain-substance not recurring, the wound soon healed. The patient made a good recovery, though some paralysis remained from the effects of the original injury.

Drs. Whipham and Myers read notes of two cases in which peculiar nervous symptoms, especially affecting the speech, occurred after variola. They had been unable to find any account of similar cases among English writers though they had found some references to the subject among continental ones. In both cases paralytic and ataxic symptoms occurred on recovery from the fever, but the most marked feature in each case was a peculiar affection of the speech. The syllables were "scanned." The onset was not sudden. There was no nystagmus and there were no tremors. The cases were therefore not examples of disseminated sclerosis. In one case complete, in the other incomplete, recovery from the paralytic and ataxic symptoms ensued. In both, however, the speech remained permanently impaired though some improvement occurred in one of the cases. The author suggested that minute scattered hemorrhages, chiefly cerebral, had occurred, and that such lesions might be more common in small-pox than in other fevers. Out of eight closely analogous cases tabulated by the authors this "scanned speech" had been a sequel in six cases in which the patients had had small-

pox. A lengthy discussion took place on this paper, in which Dr. Hughlings Jackson, Dr. Stephen Mackenzie, Dr. Barlow and Dr. Seymour Taylor, took part. Dr. Hughlings Jackson believed similar symptoms occurred without febrile disease and suggested thrombosis in a minute vessel of the medulla oblongata as a possible cause. Dr. Stephen Mackenzie said severe malaria could give rise to the same phenomenon but there was then generally tremor also.

Mr. Hutchinson described a case of necrosis of the lower jaw which he believed to have been produced by the use of phosphorus internally. The patient had taken $\frac{1}{33}$ grain of phosphorus (in pill) three times a day for two years. She had carious teeth, and inflammation had begun in connection with one of them, and probably about six or nine months after the phosphorus had been commenced.

On Monday evening, at the Medical Society of London, Mr. Edmund Owen read notes of a case in which he had performed amputation at the hip-joint by Furneaux Jordan's method. There had been abscesses in the hip- and knee-joints. Pyæmic abscesses formed in other parts, the liver was much enlarged, and the urine contained one-fourth albumin. The case did well, and when the boy (six years of age) returned from the seaside, there was a thick core of bone in the stump, and both the hepatic enlargement and albuminuria had diminished. There was a brief but lively discussion on Mr. Owen's case, and in replying he said he considered that albuminuria from scrofulous disease and crepitations at the apex of a lung were indications for operation. What would the surgeons of thirty years ago have thought of this? And yet some practitioners talk about the good old times!

Dr. Theodore Williams read notes of a case of mediastinal tumor in which unusual compression of neighboring organs was caused. There was severe dyspnœa and extreme difficulty in swallowing. The left vocal cord was fixed.

On Tuesday evening, at the Pathological Society, Dr. Percy Kidd described a case of lung disease in which (post mortem) diffused symmetrical cirrhosis of both lungs was found. There were many hemorrhages. Dr. Hanford exhibited a specimen which he regarded as one of ante-mortem digestion of the stomach.

Old Father Thames is at last to be relieved of a portion, at least, of the vast bulk of sewage hitherto poured into his channel. Within the last few years this has been tempered by admixture with a (relatively) small amount of disinfectants at the outfalls. The Metropolitan Board of Works have now prepared a scheme for dealing with the whole of the London sewage. It comprises three processes: 1, precipitation of solids by addition of lime and ferrous sulphate, $3\frac{3}{4}$ grains of the former and one grain of the latter being added to each grain of sewage and one or two hours allowed for the solids to precipitate; 2, compressing of the resulting semi-solid mass by filter presses to the smallest possible bulk, the final product (sewage-cake) being taken out to sea in large steamers if it cannot otherwise be disposed of; 3, purification of the effluent by admixture with sodium manganate and sulphuric acid. The Metropolitan Board of Works have not hitherto shown themselves particularly alive in sanitary matters, but they seem in earnest now. Their plan is being well received, and, if satisfactorily carried out, it is not too much to say that it will constitute one of the greatest sanitary reforms this generation has witnessed.

The coming extinction of private asylums, under the new Lunacy Bill, brought forward in the House of Lords, is to be opposed by those interested.

On Tuesday evening, in the House of Commons, Mr. Stansfeld succeeded in carrying his motion in favor of the repeal of the Contagious Diseases Acts. Their fate may, therefore, be regarded as sealed. Mr. Stansfeld secured a large majority—245 against a minority of 131.

OUR PARIS LETTER.

WHAT CONSTITUTES A GOOD SURGEON—HOW TO CULTIVATE STEADINESS OF HAND AND DELICACY OF TOUCH—THE MEANS WHICH SHOULD BE EMPLOYED TO PREVENT THE SPREAD OF PULMONARY TUBERCULOSIS.

PARIS, March 29, 1886.

DR. LANDOLT is a distinguished ophthalmologist, and for his age, he not being far from either side of forty, has already acquired a fame in his specialty which may be envied by many of his seniors. Like others of his colleagues, Dr. Landolt has a dispensary for eye diseases where gratuitous consultations are given to the patients of the poorer classes and demonstrations and lectures to those of the profession who may wish to attend. At the beginning of the year Dr. Landolt commenced a course of lectures on ophthalmic surgery at the École Pratique, a branch of the School of Medicine, the subject of his opening lecture being, "How to Handle Instruments in Ophthalmic Surgery." This lecture has just been published in pamphlet form, a short notice of which I thought would be acceptable to your readers. The lecturer began by indicating the points of difference that exist between ordinary and ophthalmic surgery. The difficulties attending operations on the eye are very great, but not insurmountable. As the organ we have to deal with is very small in proportion to other parts of the body its textures are delicate and it is particularly mobile. The essential requisites for an accomplished surgeon, says Dr. Landolt, are a steady hand, a clear head, good sight, and above all, self-confidence. If these qualities are necessary or indispensable in general surgery, how much more must they be in operations on such a delicate organ as the eye? In the former the whole arm of the surgeon is often called into requisition to complete a capital operation, such as cutting off an arm or a leg, whereas, in ocular surgery, this member should be altogether passive, simply acting as a lever to which the hand is suspended. But even this part of the limb is very rarely employed in ocular surgery; it is principally with the fingers that operations on the eye should be performed, and in order to render them effective they should be daily put through such exercises as will render them independent of each other, and the surgeon should cultivate that delicacy of touch and prompt manipulation which ophthalmic surgery demands. It is the fingering, added the lecturer, which makes a good ophthalmic surgeon; any movements directed by the wrist may destroy an eye. Dr. Landolt divides ophthalmic instruments into three categories, viz., instruments in handles, scissors, and forceps. Manipulation with those in the first category depends entirely on the position of the fingers on the instrument; with those in the second, the contact of the finger ought to be light and unremitting. Manipulation with forceps demands excessive freedom of the fingers, and a thorough manual command of them. It has often been said that manual exercises militate against the requirements of a good surgeon, particularly as regards manipulation. This Dr. Landolt states is an error, for, on the contrary, all that contributes to strengthen the physical and moral health of a surgeon will be of the greatest benefit to him.

At its last meeting the Council of Hygiene and of Salubrity of the Seine discussed a report submitted to it by Dr. A. Ollivier on the means that should be employed to prevent the spread or development of pulmonary tuberculosis. The following conclusions were adopted by the council: The agent, the most active in the transmission of tuberculosis, resides in the sputa. These, therefore, should never be thrown on the floor, nor on the linen, where they are transformed into dangerous pulverulent substances. Consequently phthisical patients should be recommended to spit into vases containing wood shavings. These vases should be emptied at least once a day and washed with boiling water. Their contents should be thrown into the fire and burnt. These

measures should be strictly applied to large conglomerations of persons, such as in schools, factories, barracks, hospitals, etc. In the case of a furnished room that has been a long time occupied by a phthisical patient, and particularly in the event of his death, it will be necessary to disinfect the room and the bedding with the fumes of sulphur. The clothing of phthisical patients should not be worn by other persons before being thoroughly washed in boiling water and then submitted to steam.

The next Congrès Français de Chirurgie, which will be its second session, will be held in Paris from October 18 to 24, 1886. The following are the subjects that will be discussed on the occasion: 1. The Nature, Pathology, and Treatment of Tetanus. 2. Nephrotomy and Nephrectomy. 3. Orthopedic Resections. 4. Operative Intervention in Traumatic Irreducible Dislocations.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 28, to April 3, 1886.

McElderry, Henry, Major and Surgeon. Relieved from further duty in connection with New Orleans Exposition, and ordered, on the expiration of his present leave of absence, for duty in Department of the East. S. O. 71, A. G. O., March 26, 1886.

Loring, Leonard Y., Assistant Surgeon. Granted leave of absence for one month, provided that during his absence he furnishes the necessary medical attendance at San Diego Barracks, Cal. S. O. 19, Department of California, March 24, 1886.

Hoff, John Van R., Assistant Surgeon. Granted one month's leave of absence. S. O. 29, Department of Missouri, March 29, 1886.

Banister, J. M., Assistant Surgeon. Granted leave of absence for one month, to commence on or about April 2, 1886. S. O. 63, Department of the East, March 26, 1886.

Appel, Aaron H., Assistant Surgeon. Granted leave of absence for one month. S. O. 66, Department of the East, March 30, 1886.

Johnson, Richard W., Assistant Surgeon. Relieved from duty at Fort Buford, Dak. Terr., and ordered for duty (temporary) at Fort Snelling, Minn. S. O. 28, Department of Dakota, March 29, 1886.

Official List of Changes in the Medical Corps of the U. S. Navy during the week ending April 3, 1886.

Atlee, L. W., Assistant Surgeon. Ordered to duty on U. S. R. S. Vermont.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 3, 1886:

The Late Dr. Austin Flint—In Memoriam.—At a special meeting of the Executive Committee of the New York County Medical Association the following was unanimously adopted:

Whereas, It has pleased God to remove from our Association our beloved and highly honored friend, Professor Austin Flint, M.D., LL.D., one of our founders, and an ever-willing co-worker, we desire to record the great appreciation of our loss. Professor Flint, from early manhood, has ever been an indefatigable laborer in the field of medical science, and for half a century has been one of the most accomplished teachers and writers in the profession. His varied experience, extending over different portions of our country, enabled him on his settling in New York City at once to take the foremost place in the profession. As a consultant he was without a peer; his calm judgment, urbane manners, and strict conscientiousness made his presence ever welcome to his brethren. As a gentleman, he will be held in grateful remembrance by all with whom he came in contact; his charities were proverbial. His death will be the cause of universal sorrow, especially occurring at a time when his deliberate counsels are most needed. We can never forget that genial countenance, those cheerful words, and that buoyant disposition, which, amid the greatest of sorrows, always pointed out the ray of light affording hope.

Therefore, In testimony of your respect for the deceased, it is earnestly hoped that you will attend the funeral services at Christ Church, corner of Thirty-fifth Street and Fifth Avenue, on Tuesday, March 16, 1886, at 2 o'clock P.M. The members of the Association will assemble in the Sunday-school room, entrance on Thirty-fifth Street, at 1.45 P.M.

Charles A. Leale, M.D.,
Glover C. Arnold, M.D., *President.*
Secretary.

Whereas, This Association has heard with sorrow of the death of Dr. Austin Flint;

Resolved, That in the death of Dr. Flint the profession has lost one of its brightest ornaments as a practitioner, as a teacher, as a writer, and as a man.

Resolved, That the members of this Association mourn the loss of a teacher who, during his long association of a quarter of a century with their Alma Mater, shed lustre upon her name, and whose instructions have been their safe guide in their practice.

Resolved, That above all it was the noble manhood of Dr. Flint that endeared him to his associates and pupils. In his intercourse with them there was no self-seeking, no desire for self-aggrandizement. No one ever solicited his aid at the bedside without feeling assured that Dr. Flint brought to it the resources of his learning and ripe experience, with the most sincere wish to use them for the cure, cheer, and comfort of the patient, and for the assistance of the physician.

Leroy M. Yale,
Laurence Johnson,
L. Putzel,
Committee.

The Late Dr. Alfred C. Post.—At a recent meeting of the Faculty of the Medical Department of the University of the City of New York, the following minute was adopted:

Resolved, That by the death of Alfred C. Post, M.D., LL.D., who has been for so many years a most honored and distinguished member of this faculty, and for thirteen years its president, the college has sustained a great loss which will be long regretted by its faculty, and by thousands of its alumni, both in our own country and abroad.

Resolved, That his service of thirty-five years links the name of Dr. Post inseparably with the remarkable men who founded this institution, and who won for it such a secure and influential position in the world of medicine.

As the last survivor of that distinguished faculty, he perpetuated its spirit and illustrated its traditions by his profound and varied learning, by his ability as an instructor, and by the lofty integrity of his character.

Resolved, That the faculty tenders its regretful sympathy to the members of his family, with the assurance that none appreciate better how much cause his children have to cherish a memory and a name so justly honored as that of their revered father.

CHAS. INSLEE PARDEE, *Dean.*

April 2, 1886.

THE LATE DR. CASPAR GRISWOLD.—At a meeting of the New York Clinical Society, held March 26, 1886, the following resolutions were adopted:

Whereas, One of our members, Caspar Griswold, M.D., M.R.C.S., has been suddenly removed by death;

Resolved, That we, the members of the New York Clinical Society, hereby express our sense of the great loss the Society has sustained, in common with the medical profession in general, in Dr. Griswold's death. During the several years of his membership in our Society the part which he took in its proceedings was of value to all his fellow-members, whether in the form of papers read by him, of oral contributions from his clinical experience, or of remarks in the discussions. To a frankness and pointedness of statement that always commanded attention he added a deference to the opinions of others that endeared him to all of us. By his early death we have been deprived of an esteemed and most valuable member.

Resolved, That we as a body respectfully tender to the family of our deceased associate this expression of our sympathy in their bereavement.

Resolved, That these resolutions be entered upon the secretary's minutes, on a page to be set apart for that purpose; that a copy of them be sent to the family of the deceased; and that they be furnished to the medical journals of this city for publication,

Committee.

A. A. SMITH, M.D., *President.*
B. F. CURTIS, M.D., *Secretary.*

THE LATE DR. S. W. FRANCIS.—At a special meeting of the Newport Medical Society, the following resolutions were adopted:

Whereas, Through the Providence of Almighty God, there has been withdrawn by death from the Newport Medical Society, in the very prime of life, its Vice-President, Dr. Samuel Ward Francis; and

Whereas, It is the duty of man not only to mourn with those who mourn a mutual friend, but to acknowledge and put upon record social loss and public bereavement, thereby honoring the dead and stimulating the living to more faithful following of their good example; therefore,

Resolved, That in the death of Dr. Francis the medical profession of Newport, as well as all lovers of sound learning, literature, philanthropy, indeed of all that elevates and humanizes mankind, and the whole community in which he lived, have parted with one who in every sphere in which he moved, was always a bright and shining light.

Resolved, That our colleague, the most kind, affectionate, and tender-hearted of men, ever cheerful and light-hearted under cares that would have crushed most others, constant to duty, self-sacrificing and patient, was a worthy son of the illustrious parent whose memory he so revered, and that his active, beneficent life, true to the guiding-star of a steadfast faith in our Saviour, to whom he offered its every experience, was crowned by a most lovely and enjoyable death.

Resolved, That the sympathy of the Society be communicated to the bereaved family of the deceased.

Resolved, That copies of the above resolutions be sent to the Newport newspapers and to the New York MEDICAL RECORD.

HORATIO R. STIVER, M.D.,
EZRA DYER, M.D.,
FRANCIS H. RANKIN, M.D.,
HENRY ECROYD, M.D., *Secretary.* *Committee.*

BISMARCK AND HIS DOCTOR.—Prince Bismarck is again indisposed, it is said, and pleurisy is feared. That means work for Professor Schwenniger, the Prince's doctor. Schwenniger is the Roose of Berlin. Munich was to him what Brighton was to our English rising medico, and Bismarck's eldest son was his discoverer. This gentleman, having had some sixty or seventy pounds weight taken off him, and having been brought out of the very back teeth of death by following Dr. Schwenniger's advice, suggested that his father should also become a patient. The Chancellor was willing, but he could not go to Munich, and the doctor could not leave his practice there without a *quid pro quo*. The quid—several hundred quid—was found by his appointment to a Professorship in Berlin, which he now holds, in addition to an enormous private practice. He sees Bismarck daily, had brought him into perfect health, and had so tamed the tiger that the former periodical explosions in the Reichsrath had entirely ceased, and there had been no change in the Government since Schwenniger had charge of the Chancellor's digestion. Diet, not medicine, is what Professor Schwenniger swears by. No drugs, no mineral waters, no "kur" of any kind. Eat of only one dish, no matter what that may be. Oysters, lobsters, beef, mutton—eat your moderate fill of that, but touch nothing else at a meal; no vegetables, save perhaps a little salad, no sweets, no savories, and do not touch one drop of liquid until half an hour, in some cases an hour, after your meal is ended! There is the *crux* for those who like Chablis with their oysters, Madeira with their turtle, Marcobrünner with their fish, and D. and G.'s Gold-Lack with their first entrée. One dish only, and no drink until long after the meal is over? What does Lucullus—what does Sir Henry Edwards, of the statue—think of that?—*London World.*

THE CHINAMAN FROM A MEDICAL POINT OF VIEW.—The *Southern California Practitioner* does not consider the Chinaman a healthful element in society. It says: "The Chinamen, with their opium-joints, their universal habit of using tobacco excessively, their intemperance, their venereal diseases, their leprosy, their parsimonious way of crowding together in small sleeping apartments, their concubines, their lack of the good influence on health that is exerted by wife and home, their filth, their utter disregard of all sanitary and hygienic rules, their cold-blooded heartless neglect of each other when sick or wounded, and their continuous nightly round of dissipation, have long been a serious menace to the health of every city on the Pacific coast." About the same thing can be said of the lower class of Italians, and of Russian and Polish Jews which are now being poured upon these Eastern shores.

THE "DRY-BREAD CURE" is the latest craze, and it comes from "Lindenweise." It consists of the cold pack, a diet consisting of dry bread, twice a week a little rice and barley, and three times a week Hungarian wine, all to continue for six weeks. In cases of rheumatism, gout, etc., it is said to be effectual.

ACIDS IN THE PROPHYLAXIS OF CHOLERA.—A correspondent writes that Dr. Worms, of Paris, used diluted sulphuric acid in the treatment of the premonitory diarrhœa of cholera in 1849, and again in 1853, with great success. As Koch has found that acids are prejudicial to the life of the comma-bacillus, the writer says, the enthusiastic claims of Worms would seem to have received further confirmation. As hydrochloric acid is found in the normal stomach, it is suggested that that be used in place of the sulphuric.

ON CERTAIN PROBLEMS IN THE PHYSIOLOGY OF THE BLOOD-CORPUSCLES.

THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE ASSOCIATION OF THE ALUMNI OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, APRIL 3, 1886.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

LECTURE III.

THE RELATION OF THE CORPUSCLES TO COAGULATION AND THROMBOSIS.

I PROPOSE, in this lecture, to consider the question of the relation of the corpuscles to the processes of coagulation and thrombosis, and I will first call your attention to the action of the *colorless corpuscles*. Our knowledge of the connection between these elements and coagulation dates from the observations of Buchanan in 1831. He attributed the action of what he called washed blood-clot, in inducing clotting, to the colorless blood-corpuscles included in the meshes, and which he said acted as a sort of ferment, comparing the action to that of rennet. These views have been greatly elaborated by Schmidt, of Dorpat, and his pupils, to whose researches we are indebted for an important extension of our knowledge in this department of physiology.

According to these well-known observations, the colorless corpuscles furnish the fibrinoplastin or paraglobulin, and the ferment, while the third element, the fibrinogen, exists naturally in the bloodp-lasma. Schmidt and his pupils hold that in furnishing these two elements to make up the fibrin, the colorless blood-corpuscles undergo disintegration and destruction. The evidence which they bring forward in proof of this is as follows: The blood-plasma of the horse may be readily collected by keeping the blood at a low temperature and allowing the red blood-corpuscles to subside, when a clear layer of plasma remains, consisting of plasma with a few red and many colorless corpuscles. Now, if a portion of this plasma is taken and whipped with twigs, the difference between the number of colorless corpuscles remaining in the serum and those in the original plasma represents the number of colorless corpuscles which have undergone destruction in the process of the formation of fibrin, and Schmidt and his pupils estimate that at least seventy per cent. of the colorless corpuscles undergo destruction in this way. They found that, instead of 15,000 colorless corpuscles in a cubic millimetre of the plasma before it is whipped —*i.e.*, before the fibrin is extracted—there were, subsequently, not more than 4,000 per cubic millimetre remaining in the serum. Examining the clot so obtained, it is stated that the colorless corpuscles have largely, if not entirely, undergone destruction in the formation of fibrinoplastin and the fibrin ferment. This is, perhaps, the most convincing experiment which any one of Schmidt's pupils has brought forward to sustain his view, that colorless corpuscles undergo destruction in the process of coagulation. There are many other points urged by Schmidt, to which I need not refer, as they are readily accessible in the works on physiology.

The researches of Wooldridge[1] have also shown that the colorless corpuscles play an important part in the formation of fibrin. He has been able to procure leucocytes from lymph-glands in a tolerably pure condition, by means which he has described at length in his paper. These leucocytes when added to an equal volume of a ten per cent. solution of common salt seem thus to be converted into a material resembling very closely ordinary fibrin. By experimenting with what is known as peptone-plasma he has obtained very striking results, which would appear to indicate still more clearly that leucocytes play an important part in this process. Peptone-plasma is obtained by injecting peptone into the blood-vessels and then bleeding the animal. Coagulation is prevented entirely by the influence of peptone and the red blood-corpuscles may be entirely removed from the serum by the centrifugal machine. This plasma shows no special inclination to coagulate, and is, of course, particularly suitable for experimental purposes. If the leucocytes prepared from the lymph-glands be added to this plasma coagulation at once occurs. If a small quantity of leucocytes are added the amount of fibrin produced is small; if a larger quantity is added, more fibrin is produced. In fact, Wooldridge has shown that the amount of fibrin produced in the peptone plasma is directly proportionate to the leucocytes added. The leucocytes seem themselves to form the fibrin—perhaps the entire mass, for the weight of the fibrin produced is the same as the weight of the leucocytes added. Moreover, the albumins in the peptone-plasma, after coagulation, can be shown not to have undergone any change, but remain the same, quantitatively and qualitatively; and a third point is that the leucocytes appear to have undergone disintegration.

There are other points in Wooldridge's researches to which I shall not have time to refer at length; but he concludes that it is only the dead plasma which converts the cells into fibrin, as the injection of leucocytes into the blood of the living animal produces no effect.

Such facts appear to show very conclusively that the corpuscles do undergo disintegration, and yet if the blood-plasma of the horse is examined after it has been whipped, leucocytes may be found in the serum, and also in the clot which has been produced, so that all the leucocytes have not undergone destruction. The existence of a certain number of the leucocytes after clotting has occurred has caused one of Schmidt's pupils, Heyl,[2] to divide the leucocytes into two sets: the alpha-leucocytes, which undergo destruction during clotting; and the beta-leucocytes, which remain. From observation, I do not believe that the number of the leucocytes which undergo disintegration in the clotting of the horse's blood is anything like so extensive as Heyl states.

Although the evidence in favor of the destruction of the colorless elements seems conclusive, yet if the fibrin formation is studied under the microscope, it appears to take place without any disintegration of colorless corpuscles, and it is extremely difficult to demonstrate their participation in the process. As is well known, it can be studied in a blood-drop examined in the ordinary way, or, better still, in the moist chamber. The time which elapses before coagulation begins is vari-

[1] Proceedings of the Royal Society [illegible] London, 1885.
[2] Dorpat Dissertation, Fortschritte der Medecin, 1885.

able in different individuals and under different conditions. Usually, however, from fifteen seconds to two or three minutes elapse before the first appearance of the fibrin filaments is noticed. A slide can be prepared in a very few seconds, and there is sufficient time before clotting begins to examine the colorless corpuscles, the red corpuscles, and the blood-plaques. I must say that, in a very careful examination of the process of the formation of fibrin in this way, I have never seen any appearance in the leucocytes which would indicate that, as the fibrin was formed, they underwent disintegration or dissolution. On the contrary, they seem most stable elements, and the amœboid movements persist long after the fibrin network is thick and dense in the field. Certainly in the microscopical examination of the ordinary slide, or in the examination of the blood-drop in a moist chamber, I do not think anyone has seen the direct disintegration of leucocytes in the production of fibrin. An interesting and instructive experiment is to draw the blood of a frog, or of the horse (in which Schmidt and his pupils hold that the colorless corpuscles so rapidly undergo disintegration) into a fine capillary tube in which the process of clotting can be watched under the microscope. At first, the entire tube is filled with corpuscles; but, before long, it is seen that the clot contracts, and there is a peripheral layer of serum squeezed out. In a short time, leucocytes can be seen emerging from the clot in numbers, either squeezed out or migrating from it. This experiment, which can be readily demonstrated, forms an admirable mode, as Shäfer showed some years ago, of studying the process of coagulation.

A study of the histogenesis of fibrin as seen in the moist chamber, in the capillary tube, and in the ordinary slide, affords, I think, no evidence in favor of the destruction of the colorless corpuscles, but, on the contrary, is directly opposed to this view. In a certain number of instances the aggregations of blood-plaques, to the connection of which with the process of coagulation I shall shortly refer, have possibly been mistaken for colorless corpuscles.

The relation of the *red corpuscles* to coagulation is not regarded as very important; they play a more passive part. But Landois and others have described a process which can be readily seen in the blood of the frog and in mammalian blood, examined in serum. If we take the blood of the frog and examine it in the serum of the blood of the rabbit, it will be seen that the red corpuscles of the frog crowd into columns, and in a short time the hæmoglobin leaves the corpuscles, which become granular, and fibrin filaments form in their vicinity, and, according to Landois, the red corpuscles break down into a material which resembles granular fibrin very closely, indeed. These observations were made ten or eleven years ago by Landois, and they have been confirmed by others; but whether the corpuscles undergo transformation into the fibrin filaments. or whether fibrin only clots about these groups of corpuscles under the influence, perhaps, of a ferment which they extrude, it is impossible to say.

The relation of the *blood-plaques* to coagulation is particularly interesting, and is at present attracting a great deal of attention.

In the study of fibrin formation, as seen under the microscope, it has long been noticed that the fibrin filaments spread out as distinct rays from the minute aggregations which have been known as Schultze's granular masses. Schultze noticed these, as did also Ranvier, in 1873, who regarded these masses as centres of coagulation. That the fibrin sets in a thick, dense network about the plaques is readily seen, but it can also be noticed, particularly if healthy blood is examined in which the plaques are not very numerous, that the fibrin also appears quite independently of the plaques. It forms as distinct little needle-shaped bodies, presenting an appearance not unlike that of crystals. That these crystal-like portions of fibrin appear in regions of the field quite apart from the blood-plaques, is well seen in studying the process of coagulation in the moist chamber. Although the fibrin needles, when first formed, may appear in portions of the field unoccupied by blood-plaques, yet the network is usually most dense in their neighborhood, and when the entire field is covered with fibrin filaments, the disintegrated blood-plaques look like centres from which the filaments radiate.

The relation of the blood-plaques to coagulation, as examined experimentally, is even more interesting. If an ordinary ligature is passed through the femoral vein of a dog and allowed to remain for five or six minutes, or even less, the threads become coated with the plaques, as represented in Fig. 1. It is well to separate

Fig. 1.—Aggregation of plaques on a thread of cotton passed through femoral vein of dog and allowed to remain ten minutes.

slightly the filaments of the thread, and if exposed to the blood-stream for as long as ten minutes they become uniformly beset with the plaques. A few white corpuscles may be entangled among them, but undoubtedly the plaques are the first elements to aggregate about such a foreign body. The outlines are usually distinct, but if allowed to remain long in the vein those nearer the threads become more granular, and the distinct corpuscular nature is less evident. If a small brush of thread is tied to the end of a pen-handle, or any suitable object, then whipped in the blood, as freshly drawn, for four or five minutes, and then examined, the threads will have precisely the same appearance and are uniformly covered with blood-plaques. The colorless corpuscles are adherent here and there, but the blood-plaques form the striking elements. They adhere to the filaments of the thread, and several of the finer fibres of

the thread may be entirely agglutinated by the aggregation of the blood-plaques about them. I can fully confirm these original observations of Bizzozero and Hayem, and the experiments have now been repeated by a number of observers. If the threads, after having been whipped in the blood, are carefully washed in a saline solution, all the red corpuscles can be washed away, so that few, if any, can be seen, and then if these threads are dipped into a coagulable solution, clotting will occur. This experiment was performed by Bizzozero in 1882, and has been repeated by other ob-

servers. It has been urged against it that possibly the threads beating about in the blood have absorbed some of the fibrin ferment. This is, of course, possible, but certainly in such threads the chief elements to be seen are the blood-plaques, and the leucocytes are very scanty; besides, the greater the number of the blood-plaques adherent to the thread the denser the coagulum will be, as if the blood-plaques furnished the material for the production of the fibrin or the ferment in large quantity.

Still more conclusive evidence of the participation of the blood-plaques is their relation to thrombi, as experimentally produced.

The femoral artery of a dog is exposed and a linear slit made in the vessel, through which the animal is allowed to bleed to death. This portion of the vessel is rapidly excised and placed at once in alcohol; or, still better, first in osmic acid, and then sections carefully cut through the part where the incision was made, when such an appearance as seen in Fig. 2 will be found. Occupying the cut edges, and filling in places the lumen of the vessel, a finely granular material is seen under a low power. Surrounding it, to the outside, as represented at 5 in the figure, there is a darker material made up largely of dark clots composed of red blood-corpuscles. In the central portion, in immediate contact with the cut edges of the vessel, in contact with the elastic lamina of the intima, and occupying the interstices of the ragged surfaces, are the blood-plaques. This was so stated by Bizzozero in 1882, and it has been confirmed in an elaborate investigation from the laboratory of Langhans,[1] in Berne. My own observations are in harmony with these, and we may say that the plaques are the elements which first settle on the edges of a wounded vessel, and which form the basis of the thrombus.

Fig. 3.—[illegible] Portion of Adventitia indicated at [illegible] in Fig. 2. The fibres are everywhere surrounded with granular disintegration-plaques.

Fig. 3 represents the end of a portion of the adventitia indicated by a cross (×) in Fig. 2. The sketch shows the blood-plaques in a condition of granular disintegration, but under a high power the outlines can be distinctly defined, and anyone with a knowledge of these elements and of the changes they undergo has no difficulty in recognizing them. If the cut ends of the vessel are examined when fresh, in osmic acid or Pacini's fluid, the elements are still more clearly seen, and are readily determined to be identical with those in the circulatory blood and in the granule masses. The elaborate investigations of Eberth, published in the January number of Virchow's *Archives*, 1886, clearly demonstrate that the plaques are the first elements to settle and lodge on the lacerated portion of the vessel or on a portion of vessel destroyed by acid or by caustic.

The relation which the blood-plaques bear to the so-called white thrombi is particularly interesting. Zahn[2] appeared to prove by his observations that white thrombi are composed exclusively of colorless corpuscles, and the current idea is that to a lacerated portion of a vessel the colorless corpuscles adhere and undergo disintegration, become granular, and form in this way a white thrombus. Bizzozero, Hayem, and Eberth have shown, I think pretty conclusively, that if a needle is passed across a vessel in the omentum, or in the mesentery, so as to injure it, the first elements which are collected at the site of the injury are not the colorless corpuscles, or the red corpuscles, but the blood-plaques, which form distinctly aggregated masses—white thrombi. There may

Fig. 4 [illegible]

be colorless corpuscles as well, but the chief bulk of the thrombus, which has formed at the site of the injury, is undoubtedly made up of blood-plaques.

A study of white thrombi as met with in man leads us to the same conclusion. These structures have been long recognized, and have been supposed to be made up largely of colorless corpuscles. We find them on atheromatous ulcers, forming thrombi in the femoral veins, in the auricles and ventricles, on the valves in endocarditis, and as the lining of aneurismal sacs. The examination of the superficial part of a white thrombus in osmic acid, Pacini's fluid, or even salt solution, reveals the fact that it is composed of blood-plaques in closest contact with the blood-column. So far as my observation goes, without exception, in the peripheral part where they have not undergone disintegration, such thrombi are made up of small circular, disk-like elements which anyone familiar with the blood-plaques will readily recognize as such. Fig. 5 represents two

Fig. 5.—White [illegible] aorta [illegible] Medical Gazette, [illegible] Medicine, [illegible] Medicine, [illegible] Medicine

white thrombi, more particularly the superficial parts of them in contact with the blood-current. I think they will find, without exception, that they are composed not of colorless corpuscles, nor of a reticulated fibrin network, but almost exclusively of these plaques which, in the deeper parts, have undergone granular disintegration, but in the superficial parts still retain their normal shape and appearance.

The observation that these white thrombi consisted of blood-plaques was confirmed in 1882 by Bizzozero, and in the same year by Hayem, and since then it has been noted by a number of observers.

Fig. 7 represents a small aneurism of the thoracic aorta, which shows on its lining membrane a number of soft, grayish-white curvilinear elevations, such as all observers have noted, and on examination these will be found to be made up of elements similar to those which

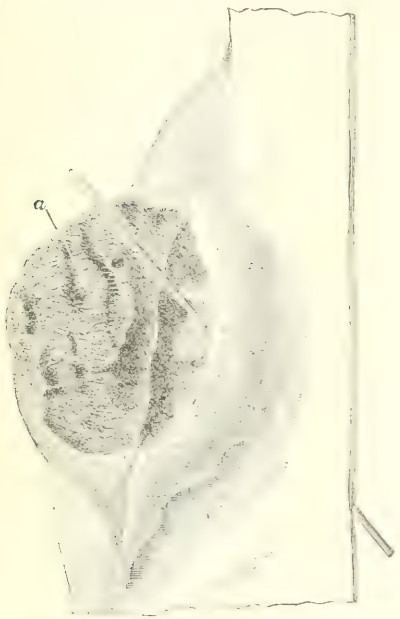

Fig. 7.—Small Aneurism of Thoracic Aorta. Showing the internal wall of the sac covered with numerous curvilinear elevations, grayish-white in color, and composed of blood-plaques. (Specimen in Museum of McGill Medical Faculty, Montreal.)

compose the white thrombi, namely, distinctly circular, disk-like blood-plaques. The changes which these bodies undergo are very peculiar. As I mentioned in my first lecture, they appear in masses as soon as they are withdrawn, and then undergo remarkable transformation, whereby they lose their outline and become converted into a granular material in which the individual plaques become unrecognizable. That change occurs in the blood-plaques as they form these white thrombi. In the deeper portion of the thrombus, represented at Fig. 5, the blood-plaques had disintegrated and become granular, and were no longer distinctly recognizable; but at the superficial part they were distinct, their outlines were well marked, and in osmic acid, in teased preparations, distinctly made out and readily preserved.

Eberth's researches are of special value in this connection, and appear to place the experimental evidence of this important point on a firm basis, and explain the production of white thrombi. In the circulating blood the blood-plaques keep with the red corpuscles. In the rapidly circulating blood the central portion of the vessel is represented by a dark line in which you see no corpuscles whatever; nothing but a red streak, on either side of which there is the so-called still layer, with an occasional leucocyte. This represents the blood-current in its active rapid condition. If the circulation becomes slower, then it is seen that, in addition to the leucocytes which collect in the still layer, the blood-plaques appear; but in the rapidly circulating blood, as seen in the mesentery or the omentum of the guinea-pig or the rabbit, the still layer, the peripheral portion, contains no blood-plaques, and only occasionally a leucocyte—in fact, the corpuscles are separated from the wall of the blood-vessels by a distinct tube of plasma.

Eberth brings forward these facts in explanation of the development of white thrombi. So long as the circulation is active the plaques remain central, and adhere neither to each other nor to the vessel-wall; but when, from any cause, the current is slow, this natural disposition of the corpuscles is disturbed, and the plaques tend to collect at the periphery, and aggregate in groups at any point which has been injured, or which has been deprived of the endothelium. Slowing of the blood-stream is, then, in this view, one of the essentials in the formation of white thrombi, and this is entirely in accord with what we know of the pathology of these structures. It is not alone the presence of intact endothelium which prevents the formation of thrombi in the vessels, for we frequently find in aneurisms, on the heart-valves, and on the aorta, denuded and rough regions upon which thrombi do not form. Indeed, thrombi are not often found on atheromatous ulcers, which would offer most favorable localities for their formation if it is the epithelium alone which prevents it. The other condition would appear to be slowing of the blood-stream, which has long been known to play such an important part, and the true significance of which is well seen in the light of these observations of Eberth.

What I contend is, that the white thrombi are composed chiefly of plaques, and that the colorless corpuscles play an altogether insignificant part in their formation, and the experimental evidence which has been offered of the relation of these structures to thrombosis is borne out completely by a study of morbid anatomy.

The further development of the thrombus results from the disintegration of the plaques, and the formation of a finely granular material in which there may be no fibrin filaments. We must recognize a granular or stroma fibrin, as Landois calls it, and a fibrillar or plasma fibrin. The former is a granular material which develops when cells undergo the peculiar metamorphosis described by Weigert as coagulation-necrosis, and it is this in reality which goes on in the white thrombi. There may be no trace of fibrin filaments, but the chief mass is made up of a granular matrix in which the outlines of the plaques are no longer visible. The stages of this transformation I have traced in thrombi of the femoral vein, and it is well seen in passing from the superficial parts to the deeper parts. The plaques on the surface of a white thrombus, as at Fig. 5, may be intact, or they may show signs of disintegration and conversion into a granular débris. The central softening of a white thrombus results from the liquefaction of the plaques, and is a result possibly of the presence of fluid in greater abundance than is necessary for the process of coagulation-necrosis. Quite recently, in a case of typhoid fever, I had an opportunity of studying the histological characters in thrombi in the femoral veins. In both they were mural, and had originated behind the valves. The attached portion was a light brown-red color, but the upper half was of a dead-white color, and the extension into the iliac was of the same character. The line of demarcation between the two was pretty clearly defined. At the thickest portion the superficial white thrombus had softened to an opaque milky liquid, but at the prolongation it was firm and consistent. A few colored and colorless corpuscles were scattered through

the white thrombus, but the great mass of it was composed of blood-plaques, and a study of the softened milky region showed clearly that the granular detritus was composed of the altered plaques. In the deeper parts the plaques became less and less distinct, until a point was reached at which the individual cells were no longer visible, and there was nothing but an indifferent matrix. The contrast in color between the outer and inner portions indicated a difference in age, possibly in mode of formation, though in the outer portion of the brown and the inner part of the white, close to the line of demarcation, the structure seemed identical.

In the light of these new observations on the connection of the blood-plaques with thrombi, the entire question may be restudied with advantage, particularly the relation of the white and mixed thrombi, and the mode of formation of the clot in aneurisms. Of the truth of the statements here made regarding the connection of the plaques with thrombosis, I feel assured from careful observation on the structure of the white thrombi (1) on atheromatous ulcers, (2) on the valves of the heart, (3) in aneurisms, and (4) in thrombi of the veins. I have not lately had an opportunity of examining a "globular vegetation" of an auricle or ventricle, but I venture to state that they are composed originally of similar structures.

NITRO-GLYCERINE IN THE TREATMENT OF CHRONIC NEPHRITIS.[1]

By FRANCIS KINNICUTT, M.D.,

NITRO-GLYCERINE, discovered by Sobrero in 1847, is a colorless (when perfectly pure), transparent liquid, with a sweetish, aromatic odor, slightly soluble in water, readily soluble in absolute alcohol and ether, soluble also in oils and fats. Its action resembles that of the nitrites. Mathew Hay [2] has shown that nitro-glycerine is really a nitrate of glyceryl, but that in the course of its decomposition by an alkali, two-thirds of its nitric acid are reduced to nitrous acid, and unite with the alkali to form a nitrite, while the remaining third is set free without reduction and forms nitrate of potash; and that such a decomposition is probably effected in the presence of the alkaline constituents of the blood and other alkaline fluids of the body. Its physiological effects have been investigated by Demne, Albers, Eulenberg, Pelikan, Werber, Tait, Lauder Brunton, Hay, Huchard, Marieux, Thompson, and others. Its physiological effects upon man, so far as ascertained, may be summarized as follows: A dose of one to ten minims of a one per cent. alcoholic solution produces, in six or seven minutes, a sensation of intra-cranial fulness, more or less intense headache, often accompanied by vertigo, ringing in the ears, and occasionally a temporary amblyopia. The cardiac pulsations become stronger, more rapid; the arteries throb violently; the pulse is accelerated; arterial tension is markedly lowered, the face flushes. The respirations are observed in certain cases to be slightly quickened. A moderate diaphoresis sometimes occurs. The lachrymal and salivary secretions are unaffected. A diuretic action is very generally claimed by English and German observers, although denied by several French investigators. The above phenomena are frequently followed by a feeling of lassitude and an irresistible inclination to sleep.[3]

In physiological doses the circulatory system is apparently chiefly affected.

The ventricular contractions become more rapid and *forcible*, the peripheral vessels dilate, arterial tension is lowered.

Dr. William C. Thompson's [1] new and valuable method of instantaneously photographing the living organs of animals *in situ* clearly illustrates the effect of nitro-glycerine upon the ventricular contractions.

One per cent. solutions applied directly to the surface of the heart, or injected hypodermatically, produce contractions, which are apparently *quite similar* in degree to those obtained by digitalis used in a similar way.

The physiological effects of nitro-glycerine upon the circulation were first conspicuously taken advantage of by Dr. Murrell [2] in his use of the drug in angina pectoris. Its efficiency in relieving the arterial tension and spasm which so frequently exist in this disease was brilliantly demonstrated and has obtained general recognition. During the past several years nitro-glycerine has been introduced gradually into the therapeutics of renal disease. I shall consider its use, first, in the treatment of those grave disturbances of the nervous system which are included under the general term of uræmia. Notwithstanding the time and labor which have been expended in the investigation of the pathogenesis of this condition, no *single* theory of the very many which have been advanced seems adequate to explain either *all* its symptoms or their occurrence in *all* cases. It seems not improbable that *many factors, acting in varying combinations and intensity in different cases*, are concerned in its production.

Increased arterial tension is so constantly associated with the symptoms of acute and chronic uræmia, that it is impossible to disregard its probable participation in their production. The assumption of arterial spasm in connection with high tension harmonizes with many of the paroxysmal phenomena of the uræmic state, and with the results obtainable from therapeutic agents which unquestionably relieve spasm.

That normal or low-blood tension and feeble heart-action not infrequently obtain at certain stages of both acute and chronic nephritis is well recognized; but in the experience of many careful observers, and certainly in my own, well-marked uræmic symptoms are absent under these conditions.

While inclined to believe that active purgation, diaphoresis, and, under certain circumstances, venesection, are oftentimes useful means for relieving uræmic symptoms, I would suggest that their action admits of a two-fold interpretation. Assuming that the retention of excrementitious products in the circulation may be *one* of the factors in the pathogenesis of uræmia, and that their elimination may be facilitated by the use of the above therapeutic agents, at the same time it must be borne in mind that relief of arterial tension and spasm also may be *directly* effected by similar measures. The remarkable power of nitro-glycerine in lowering arterial tension and relieving spasm has been referred to in the consideration of its physiological effects, and is to-day widely recognized. The uræmic symptoms, which from analogy and other theoretical considerations would seem to point especially to arterial spasm as their chief pathogenetic factor, are the well-known intense and persistent headache, asthma, and convulsions; and it is in the treatment of *these* symptoms that nitro-glycerine yields perhaps its most brilliant results.

I possess the notes of a large number of cases of uræmic headache which have been promptly and wholly relieved by the use of this agent alone. Free purgation, opium, and chloral are certainly often efficient in controlling this distressing symptom, but quite as often the relief is only temporary and their continued use is without effect. The daily systematic use of nitro-glycerine, on the contrary, is capable, in my experience, of continuously controlling this symptom, in many cases.

The comparative frequency with which an isolated convulsion occurs in uræmia may be urged as an objec-

[2] The Practitioner (London, 1883, vol. xxx, p. 428.

[3] The cumulative effect of nitro-glycerine is still under discussion.

[1] A paper by Dr. Thompson, describing [illegible] and containing some of his results, has been published since the date of writing. See Medical Record, March 13th.

[2] Lancet (London, [illegible]

tion against assigning to nitro-glycerine the efficiency in often controlling this grave disturbance of the nervous system which I believe it possesses. I have the notes of several cases in which there was no recurrence of the convulsive attack following its administration. In relieving renal asthma or dyspnœa its action has been somewhat variable in my hands. Complete relief has been obtained in certain cases, in which opium and chloral failed to procure it. On the other hand, I have seen its use unattended with any appreciable benefit. The widely varying susceptibility to nitro-glycerine in different individuals, and the duration of its effects, should be regarded in its administration. In the treatment of *acute* symptoms I have found the following the most efficient method. The initial dose should not exceed one minim of a one-half per cent. alcoholic solution, which represents gr. $\frac{1}{200}$ of pure nitro-glycerine. If no unusual susceptibility is exhibited, one minim of a one per cent. solution (gr. $\frac{1}{100}$) may be given at the expiration of a half hour, and repeated at intervals of an hour, until relief is obtained or the inefficiency of the drug is demonstrated. Two or three single doses of gr. $\frac{1}{100}$ may be given at intervals of a quarter of an hour, in the presence of grave symptoms, and then at intervals of half an hour to an hour. From the extraordinary tolerance of nitro-glycerine which is occasionally shown, I prefer at first to produce a slight feeling of discomfort (sensation of intracranial fulness, flushing of the face, slight constriction about the throat), with the single dose. Its proper strength can be thus accurately determined.[1]

During the past year papers have been published by Professor Rossbach,[2] of Jena, Burzhinski,[3] of St. Petersburg, and Lentovsky,[4] of Cronstadt, on the systematic use of nitro-glycerine in the treatment of chronic interstitial nephritis. Rossbach reports several interesting cases, in which distressing uræmic asthma, accompanied with greatly increased arterial tension, was promptly relieved, *pari passu*, with diminution in the blood-pressure, by its use in doses of gr. $\frac{1}{130}$ repeated at varying intervals of a quarter of an hour to two hours. In one of the cases morphine and chloral hydrate had failed to give relief. Œdema of the feet and bronchial catarrh, which were present, also disappeared under its use. Rossbach recommends single doses of gr. $\frac{1}{130}$ to gr. $\frac{1}{65}$, ten or fifteen times daily, at hourly intervals. Both Rossbach and Burzhinski give tabulated reports showing the effect of nitro-glycerine upon the daily excretion of urine, the percentage and actual amount of urinary albumen, and the specific gravity of the former.

Their results very closely coincide.

I append the following table, given by Rossbach, of a case of interstitial nephritis in a male, twenty-two years of age, with extraordinarily high blood-pressure and retinitis albuminurica :

Daily quantity of urine.	Actual daily excretion of albumen.	Percentage of albumen.	Treatment.
Cub. centimetres.	Grammes.	Per cent.	
4.168	14.812	0.354	
3.789	11.132	0.289	
4.350	11.[illegible]	0.2[illegible]	
4.538	13.[illegible]	0.290	Without treatment.
4.734	13.[illegible]	0.287	
5.505	17.347	0.257	
4.435	13.[illegible]	0.294	
4.068	13.[illegible]	0.277	Nitro-glycerine, gr. $\frac{1}{130}$, every three hours.
4.985	11.[illegible]	0.242	
4.810	11.149	0.232	
5.115	13.[illegible]	0.250	

Rossbach[5] deduces from his observations the following conclusions :

1. That the increased urinary excretion in interstitial nephritis must depend upon other conditions than high blood-pressure.

2. That the increased blood-pressure probably has a causal share in the production of the severe symptoms of interstitial nephritis, such as retinitis, asthma, etc.

3. That nitro-glycerine is an excellent remedy in chronic nephritis ; that it prolongs life and relieves severe symptoms.

Burzhinski[1] summarizes the results of his investigations as follows :

1. Nitro-glycerine in small does diminishes the quantity of urinary albumen passed per diem, and still more markedly the percentage of albumen in the urine.

2. The diurnal quantity of urine is perceptibly increased by nitro-glycerine, this increase persisting some time after the nitro-glycerine has ceased to be given.

3. Gradually increasing doses of nitro-glycerine influence still more decidedly the excretion of albumen.

4. With the exception of slight and transient headache, nitro-glycerine does not give rise to any disagreeable symptoms.

Lentovsky's[2] results correspond with those obtained both by Rossbach and Burzhinski. He also states that during the use of nitro-glycerine dropsy rapidly disappeared, the general condition improved, the body-weight augmented.

During the past three years I have had the opportunity of *systematically* treating a number of cases of chronic nephritis, both of the parenchymatous and interstitial (presumably) forms, with nitro-glycerine. My investigations were undertaken without preconceived views in its favor, but with the earnest desire to impartially observe its effects. The following cases illustrate the effects which I have observed from its use, upon acute and chronic (uræmic) symptoms, upon the excretion of urine and albumen in chronic nephritis, and finally upon the course of this disease.

Case I.—Miss A——, aged thirty-six. There is a history of gout on both the paternal and maternal sides. A brother died of chronic nephritis associated with gout. The patient's mother has chronic nephritis and gout. Two brothers suffer respectively from chronic nephritis and gout, and from gout alone. The patient has had a number of attacks of acute gout during the past five years. Albumen was apparently discovered in the urine prior to or about the time of the first attack, and has been present constantly since. During the past two years she has suffered from a great deal of headache and occasional attacks of violent vomiting, apparently independent of errors of diet. The patient is markedly anæmic. There is moderate cardiac hypertrophy, with accentuation of the aortic second sound. There is increased arterial tension without appreciable thickening of the radials. The urine contains a large amount of albumen, hyaline and granular casts ; specific gravity 1.008.

October 14, 1885.—The patient has suffered almost continuously since September 1st with headache, so intense much of the time as to incapacitate her for all work ; there has been more or less accompanying nausea, and on two occasions during this period violent attacks of vomiting have occurred. Arterial tension is very marked ; the bowels move freely. Nitro-glycerine, gr. $\frac{1}{100}$, in pill form, three times daily, was ordered.

October 17th.—The headache has greatly diminished. The patient says that "she feels her head," but is not made uncomfortable by it. Ordered nitro-glycerine, $\frac{1}{100}$ gr., every three hours.

October 18th.—Patient is *wholly* free from headache, the first time since September 1st. The pulse is 78, and has lost its hard, persistent character. Ordered the nitro-glycerine to be continued in the same doses. Up to the present date, four months, there has been complete freedom from headache, except on a single occasion. The patient also has been free from nausea and vomiting. The nitro-glycerine has been taken continuously in the same doses and at similar intervals.[3]

[1] Gelatine-coated pills, each containing $\frac{1}{100}$ gr., I have found quite as efficient as the alcoholic solution.

[3] The $\frac{1}{100}$ grain of nitro-glycerine produces a slight feeling of constriction about the throat, and often a slight flushing of the face in Miss A——.

Case II.—Mrs. A——, aged sixty-five, first consulted me in the autumn of 1883. The patient is the mother of Miss A——, whose history has above been given. The patient's symptoms had been referred to a disordered digestion. Examination revealed distinct cardiac hypertrophy (apex beat in fifth space, one inch outside of mammillary line), accentuation of aortic second sound, thickening of radials, and marked arterial tension. The urine contained a trace of albumen, hyaline and granular casts; specific gravity, 1.010. During the following year the patient was troubled, more or less, with severe "palpitation" and frequent attacks of violent vomiting, apparently independent of errors of diet. The urine was examined frequently; it was of uniformly low specific gravity, and was never free from a trace of albumen. The arterial tension was constantly high. Nitro-glycerine in $\frac{1}{100}$ gr. doses, three times a day, was ordered in December, 1884. The patient is a very intelligent woman, and has noticed in her attacks of palpitation that the pulse becomes "hard," and that additional doses of nitro-glycerine taken at such times have the effect of relieving both conditions. The drug has been taken continuously from the above date up to the present time—four to six times daily, in $\frac{1}{100}$ gr. doses. The patient has been under my constant observation during this period; she has had no more than two or three attacks of vomiting, the palpitation is almost wholly under control, the arterial tension is, comparatively, rarely high. The urine at times is wholly free from albumen, at times it contains a trace. Aside from a careful regulation of her life, of the bowels by means of simple laxatives, and the use of some preparation of iron,[1] no other treatment has been employed. The attacks of palpitation, inasmuch as they are uniformly associated with high arterial tension, and are as constantly relieved by nitro-glycerine, I am inclined to ascribe to temporary arterial spasm, through which increased work is thrown upon a heart already overtaxed.[2]

Case III.—Mrs. C——, aged sixty-seven, first consulted me in the autumn of 1881. She was suffering from disordered digestion, impaired nutrition, and frequent headache. The patient was anæmic. There was high arterial tension, with markedly thickened radials and temporals. The aortic second sound was accentuated, the apex beat was felt in the fifth space, three-quarters of an inch outside of the mammillary line. The urine contained a small amount of albumen, hyaline and granular casts; specific gravity, 1.009 There was polyuria. Although the patient's life was carefully regulated, and the more or less routine treatment usual in such cases employed, she grew gradually worse during the succeeding two years. Symptoms of acute uræmia, associated with great arterial tension, occurred on several occasions. Almost daily attacks of distressing uræmic asthma finally supervened, and on two occasions retinal hemorrhage occurred. In the autumn of 1883 I first instituted a systematic use of nitro-glycerine. The initial doses were $\frac{1}{100}$ gr., three times daily, almost immediately increased to similar doses every three hours. Relief of the asthma was immediate and complete, greatly to the astonishment of the patient. The improvement in the character of the pulse was marked, and was quite uniformly maintained. The general condition also gradually improved, and very fair health was enjoyed. From the above date until November, 1885, the nitro glycerine was continuously taken in the above doses, and during this period the patient was entirely free from attacks of dyspnœa and all other uræmic symptoms. The urine continued to be of low specific gravity, and to contain a small amount of albumen, hyaline and granular casts.

In November the patient paid a visit to a neighboring city. The nitro-glycerine was discontinued, contrary to my directions, a rich diet was indulged in, with little or no out-door exercise. On her return home I was hastily summoned to find the patient hemiplegic, with a pulse of great tension, severe headache, and distressing dyspnœa. The urine contained a large amount of albumen. Nitro-glycerine was again given in $\frac{1}{100}$ gr. doses, every two hours, and later every hour, ten to fifteen times daily. The headache and dyspnœa were quickly relieved, coincidently with a marked lowering of arterial tension. The patient was not purged, a daily dose of the cascara sagrada alone being given to procure a movement from the bowels. The amount of albumen in the urine rapidly diminished, attaining in a few days its former level. There has been no recurrence of uræmic symptoms. The nitro-glycerine has been given continuously; at present $\frac{1}{100}$ gr. is taken eight to ten times daily. Beyond an occasional dose of chloral hydrate to procure sleep, and iron, no other drug has been used. The striking relief of the acute symptoms, which had been present on so many occasions during a period of two years, the improvement in the patient's general condition, with the systematic use of nitro-glycerine, can only be fully appreciated by the physician in constant attendance. The result has been to convince me that in this case life has been made much more comfortable and has been prolonged by its use.

Case IV.—H. L——, aged twenty-two. Family history without gouty taint. The patient had scarlet fever when five years old, and diphtheria at thirteen years, without known renal complication. The patient has never had any venereal disease. Good health was enjoyed until January, 1885, when he suffered from an attack of cystitis. He was under the care of my friend Dr. Robert Weir, from the latter part of March. The cystitis did not wholly disappear until May. In February a large amount of albumen was discovered in the urine, with numerous hyaline casts. During the summer and autumn the patient enjoyed fair health. He was free from headache, disturbances of digestion, etc., and complained only of becoming easily fatigued after very moderate physical exercise and mental application. I was first consulted by him, at Dr. Weir's request, on October 15th. He was then slightly anæmic, but complained only of the above symptoms. On examination there was an absence of physical signs of cardiac hypertrophy beyond a slightly increased impulse. There was no appreciable thickening of the radials. The pulse was persistent, and the sphygmograph showed increased arterial tention. The urine contained a large amount of albumen and hyaline casts; specific gravity, 1.020. Specimens of urine passed at different times in the day were examined; all contained a large amount of albumen.

A careful regulation of the patient's daily life was advised, and residence in a warm climate during the winter months.

[illegible]

[1] Mrs. A—— [illegible] to take more than [illegible] gram [illegible] suffering from a feeling of fulness in the head and headache, [illegible] doses has not been established by prolonged use.

[2] It should be remembered that the [illegible] increased force of the heart's contractions, without increased frequency.

Previous to his departure I was able to observe the effect of nitro-glycerine upon the daily excretion of urine and albumen. The daily amount of fluids taken was carefully measured, and varied only within two to three ounces. The patient, throughout the period that the observations were made, was leading his usual life, taking a moderate amount of out-door exercise. The estimation of albumen excreted daily (per centage and actual amount) were kindly made by Mr. Adolph Tsheppe, whose careful work is a guarantee of their accuracy.

The foregoing table records the results of this investigation.

They may be summarized as follows :

1. The daily loss of albumen without medication was sufficiently large, presumably, to interfere with the proper nutrition of the tissues.

2. From the date of the administration of nitro-glycerine the total daily amount of albumen excreted diminished markedly and almost continuously; with increasing doses the percentage amount was similarly reduced.

3. The *immediate* effect of the discontinuance of nitro-glycerine, apparently, was to produce a marked increase in both the percentage and total daily amount of albumen excreted.

4. The effect upon the diurnal excretion of urine was to increase it moderately.

(It should be stated that on the 24th, 25th, and 26th the patient took more than his customary physical exercise, indulging in lawn tennis, and sweating profusely.)

Korkunoff[1] (St. Petersburg) has lately shown that the excretion of albumen in chronic nephritis, in individuals placed under as nearly as possible identical conditions, varies considerably from day to day, both under rest and exercise, and that this variation would seem to depend upon several factors, such as the quality and amount of sleep, upon the mental condition, etc. The above observations illustrate this point, but at the same time clearly show that the variation was slighter and less irregular during the use of nitro-glycerine than on the days when no medication was employed.

Case V.—E. R——, aged forty-five, painter by trade. Admitted to St. Luke's Hospital, January 23, 1886. Has always been a free drinker. Considered himself well until a year ago, when he suffered from a severe attack of dyspnœa at night while in bed. Similar attacks of temporary duration frequently recurred, and finally incapacitated him for work. He has occasionally suffered from a temporary dimness of vision. During the past year he has been obliged to get up at night to pass water. He has had a troublesome cough for the past few weeks. On physical examination the heart's apex beat was found in the sixth space, three-quarters of an inch outside of the mammillary line; there was marked accentuation of the aortic second sound, increased arterial tension evident to the finger, and confirmed by sphygmographic tracings, thickened radials, thickened and tortuous temporals. There was no œdema of the lower extremities, but a slight puffiness about the eyes. Subcrepitant râles were heard over the whole of the chest, in front and behind. Examination of the other organs was negative. The urine contained a rather large amount of albumen and casts—specific gravity, 1.012. Ophthalmoscopic examination showed retinitis albuminurica. The patient was markedly anæmic. There was more or less continuous dyspnœa, with paroxysmal exacerbations. The bowels were regular. Temperature normal.

From February 2d until the evening of the 7th no medicine of any kind was given. His condition remained the same as on admission. The daily quantity of urine has been very carefully measured from February 2d until the present date, February 18th, and daily estimations of the percentage and total amount of urinary albumen excreted have been made by Mr. Tsheppe. On the evening of February 7th nitro-glycerine was ordered in $\frac{1}{100}$ gr. doses, every three hours, during the twenty-four.

February 8th.—No subjective symptoms have been caused by the nitro-glycerine. There is marked improvement in the dyspnœa.

February 9th.—The patient's dyspnœa has improved still further. There is an absence of râles over the chest anteriorly; they are still present posteriorly. Ordered nitro-glycerine $\frac{1}{50}$ gr., every three hours, for eight doses daily.

February 15th.—No subjective symptoms have been caused by the nitro-glycerine, but the arterial pressure has markedly diminished. The patient has been *completely* relieved of his asthma since the 10th; says he feels better than for many months. There is still some crepitation at the bases of both lungs posteriorly.

The following tabulated report shows the daily quantity of urine passed since February 2d, with the estimations of the daily excretion of albumen :

Date.	Daily quantity of urine.	Percentage of albumen.	Total amount of albumen.	Treatment.
	Ounces.		Gms.	
February 3–4...	42	0.124	1.562	
" 4–5...	50	0.098	1.470	No treatment from
" 5–6...	20	0.056	0.436	3d to 7th.
" 6–7...	48	.....	.....	
" 7–8...	73	0.022	0.415	At 4 P.M., 7th inst.,
" 8–9...	66	0.018	0.356	ordered nitro-glycerine
" 9–10...	65	0.020	0.390	$\frac{1}{100}$ gr., every three
" 10–11...	62	0.018	0.373	hours, during the
" 11–12...	63	0.026	0.491	twenty-four.

" 13–14...	79	0.034	0.806	glycerine $\frac{1}{50}$ gr., every
" 14–15...	66	0.046	0.911	three hours, during the
" 15–16...	94	0.060	1.152	twenty-four.
" 16–17...	94	0.060	1.152	Without treatment
" 17–18...	70	0.068	1.428	from 4 P.M., 14th inst.

In this case the amount of albumen excreted daily was very small. It will be seen that both the percentage and total amount of albumen was already diminishing before the administration of nitro-glycerine, and this fact, in connection with the variations in these respects which obtain from day to day in cases of chronic nephritis, militates against a correct judgment of the effect of the drug upon the albumen excretion.

It is possible that its discontinuance may have been the cause of the immediate subsequent increase of albumen (percentage and total amount). The investigation is particularly valuable in showing the immediate and marked increase in the diurnal quantity of urine following the use of nitro-glycerine, an increase which was maintained after its discontinuance.[2]

Exact investigations of the influence of nitro-glycerine upon the daily excretion of urine and serum albumen in chronic nephritis are not yet sufficiently numerous to justify positive conclusions on these points. The daily variation in both, in individuals suffering from this disease, placed under as nearly as possible identical conditions and without medication, are very considerable in my experience, and are an embarrassing element in all investigations of this kind.

If the above results are corroborated by further observations, the interesting phenomenon is presented of an *increase* in the diurnal amount of urine, and a *decrease* in the urinary albumen, during the use of a drug which very markedly *lowers* the general blood-pressure.

I would add a few suggestions before concluding, in regard to the method of administration of nitro-glycerine, which I have found most efficient in cases of chronic nephritis.

The strength of the single dose should be just *within the limit* of producing any subjective symptoms. It can only be determined in the individual case by careful trial. This dose, in the absence of acute symptoms, should be

given four to six times daily, at equal intervals, and over a prolonged period. It is well, from time to time, to increase the strength of the single dose sufficiently to produce slight subjective symptoms, in order to ascertain whether an increased tolerance of the drug has been established by its prolonged use. On the occurrence of acute symptoms during its systematic use, it should be given more frequently in accordance with the rules already given.

I have never seen any disagreeable symptoms produced by the prolonged use of nitro-glycerine; my experience in this respect corresponds with that of Dr. Murrell,[1] who has given it daily, often in very large doses, and during a period of several years, in cases of angina pectoris.

The increased frequency of the pulse which usually follows its use is of very temporary duration.

I have occasionally observed a decided *decrease* in the pulse-rate, with diminution in arterial tension, follow its administration in critical uræmic conditions.

My investigations, so far as they have been carried, permit of the following summarization:

1. That in nitro-glycerine, given in small doses and frequently repeated, we possess a powerful agent for lowering the increased blood-pressure which is very constantly associated with the development of uræmic symptoms.

2. That it has the power to control or relieve many of the paroxysmal disturbances of the nervous system which are included under the general term of uræmia; of these headache and asthma are especially benefited by its use, the relief being more marked and continuous than that obtainable either by opium or chloral.

3. That its influence upon the daily excretion of urine and serum albumin in parenchymatous and interstitial nephritis is apparently to increase the former and diminish the latter.

4. That in the systematic and prolonged use of nitro-glycerine, in appropriate doses, in chronic nephritis, we possess a means of maintaining more or less continuously a lowered blood-pressure, of often averting or relieving critical conditions, and thereby prolonging life.

THE USE OF BROMIDE OF ARSENIC IN SKIN DISEASES.[2]

By WILLIAM THOMAS CORBETT, M.D., L.R.C.P. Lond.,

PROFESSOR OF DISEASES OF THE SKIN IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF WOOSTER, CLEVELAND, O.

Having almost unconsciously drifted into some of the journals[3] in connection with the use of the bromide of arsenic in certain diseases of the skin, it may be of sufficient interest to give more in detail my limited experience with the drug.

In the first place, it is of prime import that we have a definite idea as to what we are giving when we prescribe the arsenious bromide. It is formed from the two elements in the presence of carbon disulphide; it is colorless, crystalline, and of a peculiar garlic odor. It is deliquescent and on contact with water is instantly decomposed, arsenious acid (As_2O_3), or white arsenic, and hydrobromic acid (H. Br.) being formed; therefore the arsenious bromide, as found in the shops, is incompatible with water, be it ever so little, and dangerous as a medicament.

A solution of bromide of arsenic introduced many years ago by Dr. Clemens, of Frankfort-on-the-Main, the formula of which is published in the "National Dispensatory," contains one part each of arsenious acid and pure potassium carbonate dissolved in ten parts of boiling water, to which eighty parts of water is added and two parts of bromine. After this liquid has become colorless by standing, sufficient water is added to make one hundred parts, which makes it of the same arsenical strength as Fowler's solution. But this solution, according to trustworthy authority, consists of bromide and arseniate of potassium. Mr. Hoppe informs me that "in Clemens' solution the bromide of arsenic cannot exist as bromide of arsenic, it being decomposed by contact with water." The solution of this question, however, belongs to the domain of the chemist; let me say a few words as to the therapeutic effect. Clemens' solution was first given to the profession in 1860 (*Gazette des Hôpitaux*, No. 11).

Later, in 1875 ("Ziemssen's Cyclopædia"), Dr. Hertz recommended it in chronic malarial poisoning; he adduced in its favor that it could be taken a long time without producing unpleasant symptoms. From its supposed chemical status it is quite probable that it might.

The only real solution of arsenious bromide which I have met with is the alcoholic solution recommended by Dr. H. G. Piffard.[1] He directs that one part of arsenious bromide be dissolved in one hundred parts of alcohol, of which one to two minims may be given in a wineglass of water after meals. Of late I have used the following formula prepared for me by Mr. Louis Hoppe, to whom I am indebted for some valuable and timely suggestions relative to the drug:

℞ Arsenici bromidi (Merck's) ..... gr. j.
Alcoholis ..... ʒ ij.
Solve et adde
Elix. simplicis ..... ʒ viij.

M. Sig.—A teaspoonful to be taken in water after meals, gradually increased.

The bromide of arsenic was first employed in the treatment of cutaneous diseases by Dr. H. G. Piffard, who, in 1881,[2] spoke favorably of its use in acne; since then little has been said of it. My first experience with the arsenious bromide—or what I thought to be arsenious bromide—was in a rather obscure case of psoriasis[3] which I saw through the courtesy of Dr. Z. T. Dellenbaugh. The patient was taking Clemens' solution in two minim doses after meals, to which chrysarobin (grs. xv. to vaseline ʒ j.) was suggested as an external measure, whereupon the eruption cleared up and to my knowledge has not returned since. The favorable termination of this case in about eight weeks, after it had resisted able treatment other than the combined use of Clemens' solution and chrysarobin, induced me for a time to follow this method in all cases of psoriasis. To determine the relative value of the two drugs, in September, 1884, four cases were treated with the internal use of Clemens' solution, gradually increasing the dose to six minims, and four other cases with the inunction of chrysarobin. It did not take long, however, to settle the point as to their relative value; of the first series some improved slowly, others not at all, and the result was unsatisfactory; whereas the second series, or those using the chrysarobin inunction, improved as readily as the cases previously treated with the internal and external methods combined. Since then I have used the formula herein given, but with what success I am not prepared at present to say. My impression is that psoriasis treated with the alcoholic solution of arsenious bromide is less liable to return than it is when treated solely by external means—but of this later.

In acne vulgaris marked improvement has followed its use in my hands, but only in cases of reflex origin, as I take it, from undue irritation of the reproductive organs in neurosthenic persons. A marked case of this kind was reported in the *Columbus Medical Journal* of October, 1883, in which acne appeared in a female aged twenty, at the time of her becoming a *fille de maison de joie*; this patient returned to the Dispensary for Skin

[3] Jour. Cut. and Ven.

Diseases from time to time, but treatment proved unavailing until, September, 1885, she was given arsenious bromide, gr. $\frac{1}{60}$ increased to gr. $\frac{1}{45}$, when she made a speedy recovery. For a time there was a tendency for the disease to return at each menstruation, but this yielded to the increased dose last given.

In another case of a like nature, in a male aged nineteen, who contracted gonorrhœa, the history shows the following points of interest: The active discharge from the urethra subsided into what the patient termed the "gleet," accompanied by a copious eruption of flesh-worms" on the forehead. I saw him for the first time in August, 1885, at which time the urethral discharge had disappeared, but the acne, in spite of treatment, was persistent. The patient thought a vestige of the "gleet" still remained, as the lips of the meatus were sometimes adherent of a morning. A No. 24 French sound passed into the bladder readily and without pain, although the entire tract was hyperæsthetic, whereupon I assured him he had nothing to fear from gleet.

He was directed to keep the forehead clear of comedones by squeezing them out daily, and to apply the following lotion at night:

℞. Hydrargyri chlor. corrosivi..... gr. iij.
Glycerini..... ʒ iv.
Tinct. benzoini..... ʒ iv.
Aquam rosam adde..... ℥ vj.
M.

This he followed faithfully for six weeks, and returned worse than before; he was then put on the arsenious bromide, gr. $\frac{1}{80}$, as an additional measure, and directed to continue externally as before; a fortnight afterward the acne began to improve; a week later it was found necessary to increase the dose, which was gradually increased to gr. $\frac{1}{60}$, and finally to gr. $\frac{1}{45}$, before recovery was complete. The treatment produced no marked gastric disturbance at any time, and the patient said he had never felt better. Time of treatment with the arsenious bromide, nine weeks. There has been no return of the disease since. In pruritus hiemalis, or winter-prurigo, the drug seems to be of equal, if not greater, service. The treatment of this affection, which is so common along the chain of lakes, has given medical men more annoyance and less reputation than almost any other affection. External treatment may relieve for the time, but the average patient, according to my experience, objects to spend much time frescoing his legs when the objective symptoms are so slight; besides, the paroxysms in the more severe cases come on during sleep, when the finger-nails are applied unconsciously. For two or three winters preceding the present a number of cases under observation have taken the potassium bromide with but partial success, because it was found extremely difficult to get them sufficiently under its influence for a malady that gave annoyance only once or twice within the twenty-four hours. Less inconvenience and better results were noted to follow the use of hydrobromic acid, yet here again the full therapeutic effect was objectionable.

Theoretically, in October last, the bromide of arsenic was given two patients who had yearly, upon the first approach of frost, suffered from pruritus; the treatment was begun several weeks before the usual advent of the disease, beginning with gr. $\frac{1}{60}$ after meals; as the weather grew cooler the dose was increased to gr. $\frac{1}{60}$, which had been maintained in one case to within a fortnight of the present writing, the patient remaining entirely free from the pruritus. In the other two or three slight attacks have followed prolonged exposure to cold, but these were allayed by the local use of liquor carbonis detergens (℥ ss. to ℥ iv.), which had previously been used without benefit.

In two other cases in which treatment was applied for after the discomfiture had become sufficiently severe to prevent sleep, it was found necessary, in addition to the arsenious bromide, to employ a solution of caustic potash (gr. x.–xx. to ℥ j.) externally to give immediate relief.

In brief, I have endeavored to outline a few instances in which the use of bromide of arsenic has, to all appearances, fulfilled what other drugs have repeatedly failed to accomplish; at the same time I am well aware that impressions rather than opinions are justifiable from the meagre data at my disposal. In the *neuroses cutaneæ*, which American physicians are destined to encounter more, and to more fully appreciate, there is a dearth of drugs to meet certain indications which are brought to light by the unravellings of clinical and pathological research; in this direction it seems to me the one under observation will find its proper scope.

SIMPLE DISLOCATION OF THE FIBULA.

By JAMES H. PARKINSON, M.D.,

SACRAMENTO, CAL.

The following case, which occurred in the practice of Dr. W. A. Briggs, of this city, is apparently unique:

T. P——, aged twenty-four, robust and well developed, in wrestling with a companion fell with the right foot adducted and resting upon its outer aspect, the knee being adducted and slightly flexed, his antagonist falling on the limb. A loud snap was clearly audible; on rising he found it impossible to walk; severe pain was felt in region of knee, and a "lump" noticed on the superior tibio-fibular articulation. When seen within half an hour after the accident no swelling had taken place. The head of the fibula was found to have been dislocated backward; the tumor formed by the displaced bone was plainly defined. The external lateral ligament of the knee-joint was intact, and could be felt tensely stretched from bone to bone. No movement was detected, the fibula being firmly fixed in the abnormal position. Reduction was attempted by pressure on the head of the bone from behind forward, with the limb in the flexed and semi-flexed position, aided by rotation of the foot inward; also by flexing and suddenly extending the limb, but without any apparent effect. The pressure necessary being unbearable, ether was administered, and attempts at reduction were renewed without success; finally the leg was flexed on the thigh until the heel touched the posterior surface. Firm pressure, in the manner already described, was again made, and it was thought that the bone could be felt moving. While this was being maintained pressure was applied to the head of the bone directly inward, when it slipped in with the characteristic snap.

Luxation of the head of the fibula is very uncommon, and but few cases are recorded.

Fergusson (American edition, p. 288) deems the accident to be "so rare, and in all likelihood accompanied with fracture," as not to require separate comment. "This is a rare accident, due, according to Bryant, to violent adduction of the foot and abduction of the knee, and is reduced by firm pressure over the head of the bone" ("The International Encyclopædia of Surgery," vol. iii., p. 705).

Bryant (2d edition, vol. ii., p. 347) mentions having only seen three cases, and from the absence of any directions as to reduction, evidently met with no difficulty.

Erichsen (7th edition, vol. i., p. 512) as occasionally, though very rarely, met with, Boyer and Sanson having each recorded one. In his own case the injury had not been seen till some time after the accident, when "the tension of the tendon of the outer hamstring effectually prevented any attempts at reduction.

Gant has seen one instance of displacement forward, and refers to three cases described by Malgaigne.

Hamilton (3d edition, p. 714) mentions three cases only; one by Sanson, one by Debreuil, and one by Richardson.

Holmes ("System of Surgery," 2d edition, vol. ii., p. 917) says that the accident is occasionally met with.

Gross (vol. i., p. 1132) states that there are few examples on record, and cites Boyer's case.

Cooper (p. 199) had two cases, in both of which reduction was easy.

The foregoing summary shows the lesion to be very infrequent, rarely occurring in its simple form, but most usually as a complication of some graver injury.

This case is remarkable for the extreme difficulty presented in reduction. The principal opposing force appeared to be the external lateral ligament, which bound the head of the bone down to the surface of the tibia. This seems evident from the fact that the only procedure by which it was possible to relax it ultimately reduced the displacement.

Clinical Department.

INTRA-UTERINE ASCITES.

Dr. W. F. Morgan, writes: "The case of 'ascites developed in utero' reported in The Medical Record of March 13th, recalls one which happened in my own practice about eighteen years ago. The mother was colored, and a primipara; labor was tedious, and the fœtal heart-sounds were absent. After the head and shoulders were born, a delay occurred which caused me much perplexity until the cause was ascertained. The fœtus had apparently been dead for some days. Dr. Samuel Phillips tells me that he has met with one case of fœtal ascites in a practice of thirty years. The child was of enormous size, was hydrocepalic, and was still-born The cord was nearly as large as the wrist. The mother was colored."

PERMANGANATE OF POTASSA — AMENORRHŒA.

Dr. Lee O. Rodgers, of San Francisco, reports the following case in corroboration of the article of Dr. Billington in The Medical Record of March 6th: "Miss F——, aged nineteen, was sent to me for advice, and gave the following history: She leads an active life when at home, spending much time in the open air. In July, 1884, she came to a town adjacent to this city on a visit to friends. She began shortly after to grow 'stout,' her abdomen particularly becoming prominent. Her menses disappeared entirely after the period in July, previous to which she had always been perfectly regular. In March, 1885, she was sent to me by her hostess, who thought her pregnant, for the purpose of being kept in the city and confined. The girl seemed to be remarkably healthy and was very 'fat,' and she proved, upon physical examination, to be a virgin. I immediately put her upon potassium permanganate, a two-grain compressed tablet, four times a day, each tablet to be followed immediately by a large gobletful of water. Much nausea and some vomiting occurred during the administration of the medicine, but I attributed this to the fact that I gave the tablets on an empty stomach, as I accepted Bartholow's theory of the action of the drug. On the fourth day of the administration of the permanganate the menses appeared and lasted four days, after which the patient was sent to her home. She was instructed to inform me if her menses failed to appear on time after her return home, but I have not heard from her."

COLD WATER COMPRESSES IN SPASMODIC CROUP.

Dr. J. T. Jelks, of Hot Springs, Ark., writes: "In your issue of February 27th appears an extract from the *Therapeutic Gazette* concerning the efficacy of cold water compresses in affections of the respiratory tract. The cold water compress in spasmodic croup is one of my earliest recollections, my brothers and myself having been sufferers from this distressing disease, and I many times witnessed and felt the speedy relief afforded by cold water. In a practice of fifteen years I have never given a dose of medicine of any sort for the relief of spasmodic croup, and claim that there is no necessity for giving alum, turpeth mineral, aconite, or, indeed, any remedy whatever. A napkin or handkerchief is wet in cold water and wrapped about the throat, and over this is applied a dry towel. In ten or fifteen minutes the child will be breathing easily and will probably be asleep. This seems to be an exceedingly simple thing to do when the family and patient are in such distress, but it has always been successful in my hands."

A CASE OF OVARIOTOMY WITH SOME PECULIAR FEATURES.

Dr. A. R. Smart, of Hudson, Mich., reports the following case: "The patient, aged twenty-six, had noticed a gradual enlargement of the abdomen for three years, and it was now the size of that of a woman at full term. There was moderate emaciation and the patient presented the cachectic appearance commonly associated with well-developed ovarian cysts, but was otherwise apparently in fair health. A diagnosis was made of unilocular cyst of the right ovary, and an operation was determined upon. Upon incision the peritoneum was found closely adherent to the tumor, and even after the opening was prolonged above the umbilicus, no line of separation could be found between the tumor and the abdominal wall. The cyst was not tapped, but was drawn out, being stripped from the adherent peritoneum during the process. A separation was thus gradually effected between the tumor and the abdominal wall, arch of the colon, and portions of omentum, several vessels and vascular bands requiring ligature, until the deeper attachments were reached. It was now found that the cyst-wall was firmly adherent to the brim of the pelvis, to the posterior surface of the uterus and to a small portion of the bladder. The adhesions to the uterus were carefully broken, when the patient was seen to be suffering from shock, and it was deemed best to abandon further efforts in this direction. The contents of the cyst were removed as carefully as possible and the wall brought out at the lower angle of the wound and secured by two sutures passing deeply through the abominal parietes. The cyst was then cut away leaving a portion, the size of the thumb, protruding half an inch above the surface of the abdomen. The carbolized silk-ligatures within the abdomen were cut short, and the cavity was cleansed, as well as possible, of clots, and some sero-purulent fluid which had escaped from the cyst through a rupture in its wall. The wound was closed by sutures including the peritoneum, a drainage-tube was passed deep into the pelvis, and an antiseptic dressing applied. The operation lasted one hour and a half. The patient recovered soon from the symptoms of shock. At the end of four hours about four ounces of bloody serum were withdrawn through the drainage-tube, and this was continued for six days, the quantity continually lessening. Injections were made into the abdominal cavity every day until the discharge ceased. The drainage-tube was removed on the seventh day. The stump ceased to discharge on the eighth day when it had sunk a little below the surface of the abdomen. The temperature rose only once to 103°, and the patient progressed steadily to complete recovery. No spray was employed, but the strictest antiseptic precautions were used." Dr. Smart writes: "This case is of value in its bearings upon the most desirable disposition of portions of the cyst which, for any reason, it is thought best not to remove. After completing the operation my mind was troubled about the outcome of the cyst-stump, and I regretted that I had not placed a drainage-tube in it so that I might have irrigated its cavity, but the result proved the uselessness of such procedure."

Progress of Medical Science.

A Result of Extension in the Treatment of Fracture of the Thigh.—Dr. Fischer reports a case of fracture of the thigh in a child six years of age, which was treated by extension with weight and pulley. A cure was obtained in four weeks, but it was then found that the ligaments of the knee had been so stretched that the ends of the tibia and femur slid over each other with an audible sound, and hyper-extension occurred when an attempt was made to stand. The trouble was relieved by retention for a month in a silicate of soda splint. The cord passed over two pulleys and a weight of eleven pounds was used. Dr. Schmidt, in referring to this case, reports a similar instance of over-stretching of the knee in an old woman, with fracture of the femur just above the condyles. In both cases the trouble was due to the continuous traction maintained by plasters attached only to the leg and pulling through the knee-joint.—*Centralblatt für Chirurgie*, January 23, 1886.

Epidemic Hemeralopia.—Night-blindness is a symptom met with in many affections of the fundus of the eye, and especially in pigmentary retinitis; but it is also met with as an epidemic condition especially among soldiers. M. Laveran relates that an epidemic of this sort, occurring at Besançon in the spring of 1855, was so severe that it was found necessary to send out parties every day at sunset to lead back to the barracks those who had been overtaken by nightfall and were unable to find their way. The disease never affects officers or those subalterns who enjoy a relative degree of comfort, such as the musicians, but attacks chiefly the common soldiers. It has been supposed that hemeralopia was due to the effect of bright sunlight, or of the reflection from snow or sand; others have attributed it to the sudden lowering of temperature at sundown, and others again have regarded the symptom as an expression of latent scurvy. It has recently been asserted that night-blindness was caused by fatigue of the retina, but this does not account for the fact that certain classes only are attacked, and that others who make no less use of their eyes are exempt. M. Laveran classes it among the diseases of alimentation, and thinks it is caused by a deficient supply of animal and fatty foods. Dr. Eugène Martel, in an article of which this is an abstract, published in the *Revue Internationale des Sciences Médicales* of January 31, 1886, says that he has never found any constant changes on ophthalmoscopical examination; there may be a serous infiltration of the retina, a spasmodic contraction of the arteries, venous congestion, etc., but no lesions of such frequent occurrence as to deserve special mention. Weber has noted dilatation of the pupil and epiphora, and the connection of these symptoms with night-blindness seems to be a pretty constant one. Dr. Martel's theory is that epidemic hemeralopia is simply the first stage of sleep, in which the sight is dimmed and the eyelids fall. He says that the affection is observed only in soldiers who are obliged to undergo considerable fatigue, are exposed to the cold, and who receive an insufficient amount of flesh meat in their rations. He relates the case of a man who had attacks of apparent blindness, occurring during the day as well as at night. He could discover nothing abnormal in the fundus of the eye, but, meeting his patient one day in the street, noticed that his eyes were half closed; he could raise the lids perfectly, but did so with a certain effort. Appropriate treatment effected a speedy cure. The results of treatment in hemeralopia also lend some weight to this theory. Cod-liver oil, strychnine, and rest are found sufficient to effect a cure in most cases. The oil removes the condition of inanition, strychnine is a general tonic and muscular excitant, while with rest the patient gets a sufficient amount of sleep and is not troubled with the first unconscious stage of this process as night falls. In a recent number of *Vratch*, Dr. Roussanoff states that all the inhabitants of a little village of Southern Russia, built upon marshy ground, suffer every spring from hemeralopia. As soon as they notice the symptom they begin to take cod-liver oil, and the night vision is usually restored in two or three days. Of all the inhabitants of the village treated in this way, for five years in succession, only two have been found who were not cured by the oil.

Diagnosis of the Sex of the Fœtus from the Number of Cardiac Pulsations.—Dr. Juan Bidart asserts that a certain relation exists between the sex of the fœtus in utero and the rapidity of action of the heart, by which it is possible to determine almost with certainty whether the infant be male or female. When the pulsations are below 135 to the minute the child is a boy, and when from 135 to 145 it is a girl. In one hundred cases in which he made observations on this point, he foretold the sex correctly ninety-two times.—*Deutsche Medicinal-Zeitung*, January 21, 1886.

Joint-Inflammation Occurring with Purulent Ophthalmia.—Dr. Lucas reports the case of a child, eighteen days old, who suffered at the same time from purulent ophthalmia and inflammation of the left knee and wrist. The mother had had a purulent discharge from the vagina for some days before the birth of the child, and the affection of the eye was undoubtedly the result of direct infection. M. Debierre reports a similar case of a child suffering from severe suppurative inflammation of both eyes. On the twelfth day of the disease the child was seized, without the occurrence of any traumatism, with severe pain and swelling of the left elbow. The inflammation developed like gonorrhœal rheumatism and subsided slowly after about three weeks. These joint affections were most probably attributable to the purulent inflamnation of the conjunctiva, and, like gonorrhœal rheumatism itself, should be regarded as infectious in their nature.—*Journal de Médecine et de Chirurgie Pratiques*, January, 1886.

Aphonia Caused by Morphine.—Dr. Trevelot reports the following case in the *Journal de Médecine et de Chirurgie Pratiques* for March, 1886. Being called to see a young man, nineteen years of age, suffering from delirium tremens, he gave him morphine in doses of from one-fourth to one-third grain hypodermically. The attacks were speedily relieved, but each injection was followed by complete aphonia. The patient moved his lips, but could not enunciate at all, and the voice returned only after the expiration of twenty to thirty minutes. The same phenomenon was observed during a second attack when morphine was made use of; but in a third seizure, when the drug was not employed, aphonia did not supervene.

Malignant Tumors of the Fauces.—The following are the conclusions of M. A. Castex, in an article on this subject in the *Revue de Chirurgie* for January and February, 1886: Malignant tumors of the fauces are most frequently epitheliomatous in nature. They usually originate in the tonsil. They appear generally in later adult life, but it is not possible to attribute their occurrence especially to the use of tobacco. The most marked functional symptoms are pain in the ear, ptyalism, and difficulty and pain in deglutition. Among the objective characteristics may be noted the tendency of the ulceration to spread on the surface rather than to increase in depth, the grayish and pulpy mass which covers the ulcer, the peculiar shapes (sometimes as if flattened out, and sometimes in disseminated islets) which the neoplasm assumes, occasionally anæsthesia of the pharynx, and enlargement of the glands at the angle of the jaw. The general symptoms are relatively late in manifesting themselves. The progress of the disease presents frequent remissions, and the neoplasm spreads usually along the pillars of the fauces, and then over the veil of the palate. Certain epitheliomata of the pharynx have a boring tendency, and perforate the base of the skull. Adenomata of the velum, at first encapsulated, may rupture their en-

velope and take the course of sarcomata. Secondary adenopathy is often slow to appear in epithelium of the pharynx. As regards diagnosis, any unilateral hypertrophy of the tonsil in those advanced in age should be regarded with suspicion. It is sometimes difficult to decide between cancer and the tonsillar manifestations of syphilis in any of its stages, especially chancre of the tonsil. The diagnosis between malignant disease and the tuberculous and scrofulous lesions of the fauces is more easily made. As regards surgical interference, M. Castex formulates the following rules: 1. When the neoplasm is circumscribed and the neighboring glands are not involved, an operation should be performed; 2, intervention will also do good rather than harm when, although the disease is extensive and the glands are affected, the tumor is nevertheless circumscribed and movable; 3, when this degree is exceeded an operation can be but palliative in its result, and is justifiable only when the pain is excessive or other imperative indications are present. Access may be gained to the seat of disease either through the natural openings or by incision from without, but in either case free drainage to the exterior should be provided for. As a rule, M. Castex concludes, if the operation be performed early and the entire neoplasm be removed, a considerable period of comfort and freedom from the disease will be obtained, but it is very important to intervene at as early a period as possible. The operation itself is not wholly free from the dangers of hemorrhage, secondary pneumonia, and septic infection.

Incontinence of Urine Caused by Nasal Stenosis.—Dr. Ziem confirms the statement made by Dr. Major, of Canada, that nocturnal incontinence of urine occurs very frequently in children who are forced to breathe through the mouth by reason of some nasal obstruction. He rests his assertion upon some cases recently observed by him, and he regards it as very probable that the infirmity might be cured by the re-establishment of the normal mode of respiration. The author endeavors to explain the relation existing between buccal respiration and nocturnal incontinence of urine by regarding the latter as due to insufficient hematosis and a consequent accumulation of carbonic acid in the blood.—*Journal de Médecine de Paris*, February 21, 1886.

Oil of Santal in Urinary Affections.—Dr. A. P. Gipoulou writes, in the *Journal de Médecine de Paris* of February 14, 1886, concerning the good results obtained by him from the use of the oil of yellow sandal-wood in the treatment of the various affections of the urinary organs. The results of his experiments may be tabulated as follows: 1. In chronic and obstinate gonorrhœa no especially remarkable effects were produced. 2. In acute gonorrhœa accompanied by severe vesical tenesmus, frequent and painful micturition, etc., the acute symptoms were speedily relieved, though the discharge diminished only gradually in quantity. 3. In a case of suppurative nephritis of the left kidney, in which there was frequent micturition, and the urine was loaded with pus, an improvement was noted within twenty-four hours, and at the end of a fortnight the pus had entirely disappeared from the urine. 4. A railway employé was suffering from acute cystitis, accompanied by tenesmus and bloody urine, which had resisted the action of ordinary remedies for over a month; he was relieved permanently in a few days by the use of yellow sandal-wood oil. 5. In a number of cases of vesical catarrh equally rapid and permanent results were obtained. 6. In three cases of simple acute unilateral nephritis speedy relief was afforded by the same remedy. 7. In two cases of nephritic colic excellent results followed the administration of santal oil; the attacks were promptly cut short, and an apparent cure was the result. 8. Finally, Dr. Giloupou relates a case of acute Bright's disease following scarlet fever, in which there was general anasarca and the urine was heavily loaded with albumin. During a treatment for four or five days with diuretics the œdema increased, but within two days after giving santal oil the improvement was marked, and at the end of a week the anasarca had disappeared and no more albumin could be found in the urine.

Belladonna as a Corrective of Iodide of Potassium.—Dr. Aubert employs belladonna as a preventive of the unpleasant effects produced by iodide of potassium upon the naso-pharyngeal mucous membrane. One-half of a grain of belladonna administered with the iodide is sufficient to prevent these disagreeable symptoms. It is unnecessary to continue the belladonna for a great length of time, for in a little while the mucous membrane ceases to be sensitive to the action of the potassium salt.—*Journal de Médecine de Paris*, February 14, 1886.

Acute Rheumatism in Mother and Child.—Dr. Schaefer reports in the *Berliner Klinische Wochenschrift* of February 1, 1886, of a woman who gave birth to a child while she was suffering from an attack of acute articular rheumatism. Delivery was speedily accomplished, but had no apparent influence upon the course of the fever nor upon the articular affection. Five days later the infant was also seized with fever and a painful swelling in several of the joints. The course of the disease in both mother and child was a very protracted one and rebellious to the action of the usual remedies. The writer believes that the disease in the child was due to infection from the mother during intra-uterine life, and regards the case as conclusive proof of the infectious nature of acute articular rheumatism.

Treatment of Scrofulous Ozæna by Turpentine.—Dr. G. Malacrida writes in the *Gazetta degli Ospitali* of March 7, 1886, concerning the excellent results obtained by him from local applications of oil of turpentine in scrofulous ozæna. After cleansing the nostrils with a solution of chloride of sodium and drying the mucous membrane with pledgets of absorbent cotton, he introduces a bit of cotton moistened with a few drops of the essential oil of turpentine. In a number of cases in which this method was employed the disagreeable odor was almost immediately destroyed, and a permanent cure was obtained within less than a month. The first applications having caused considerable pain and irritation, the author subsequently adopted the precaution of covering the cotton containing the turpentine with a thin, dry layer of the same material, and found the good effects in no degree lessened by this procedure.

Spontaneous Evolution of a Living Child at Term.—Dr. E. Lvoff reports the following rare case in the *Russkaya Meditsina* of February 9, 1886. The woman, a strong, well-nourished peasant, thirty-five years of age, had given birth to six children by normal head-presentations. At the birth of the seventh child, after the bag of waters had ruptured, a hand came down. The midwife thought, however, that there was no occasion for alarm, and did not send for assistance until four hours had elapsed. When the writer was summoned, he found a transverse presentation with the left hand down in the vagina. The head lay high up on the right side, the back of the child was directed forward, and the breech was to the left and rather tightly wedged into the entrance to the true pelvis. The child was alive, and the pulsations of the heart were distinctly audible. The pains were strong and frequent. Just as Dr. Lvoff was about to introduce his hand to turn, during a severe pain, the breech slipped a little and came into the outlet, while the head passed upward. After this the labor was quickly terminated without assistance, and a living child, weighing nine pounds, was delivered. Spontaneous evolution is not very infrequent in the case of a dead or immature child, but it exceedingly rarely happens that a well-developed living child is born in this way—indeed, some writers have denied that such a termination is possible.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 17, 1886.

THE CAUSE AND PREVENTION OF DIABETIC COMA.

THE two most frequent causes of death in diabetes are phthisis and diabetic coma. In young persons, and those confined too exclusively to a meat diet, it is coma which most frequently ends the disease. This coma is sometimes uræmic, and sometimes that of a cerebral apoplexy, but in the great majority of cases it is neither, but a peculiar state characteristic of the disease. It is natural that this peculiar and fatal incident of diabetes should receive much attention, and this has been the case, especially since Petters, in 1855, and Kaulich, in 1860, noted the fact that, in many instances, the urine and breath of comatose diabetics exhaled a peculiar odor due to acetone, and since Kussmaul, in 1874, gave some solid support to the view that the coma was due to the accumulation of acetone in the blood and tissues.

Since Kussmaul's article appeared, a great many contributions have been made, some bearing out and some entirely opposed to the view of a toxic coma from acetone. Some positive evidence against the acetone theory has been furnished by Frerichs, who gave acetone in doses of gr. xx. to gr. xxx., without causing any severe symptoms. Albertoni also gave as much as an ounce and a half to a man, without producing any symptoms but that of stupor. Frerichs has said that the term acetonæmia should be expunged from pathology. He was inclined to believe, however, that the coma was a toxic one due to some products allied to acetone. Some authors have attributed diabetic coma to the presence of an excessive amount of fat in the blood (lipæmia), with resulting pulmonary embolism (Sanders and Hamilton, 1877). Fitz and Starr, who have observed the lipæmia, have not been able to attribute to it the coma.

Ebstein believed that the saccharine blood caused a necrosis of the renal epithelium, with consequent imperfect elimination of acetone, and that the kidneys are primarily at fault.

Abeles has found, in some diabetics dying of coma, a hyperglycæmia of the brain-tissue, while Scott, Donkin, Schmitz, Paget, and Dickinson, found an atrophy of the heart so great, that in some cases diabetic coma might be attributed to a weakness and failure of this organ.

With so many conflicting views and so much contradictory evidence, it might well seem difficult to come to any definite conclusions.

Still this is not perhaps impossible. It will be admitted at once, that some cases of diabetic coma are simply cases of uræmia or of cerebral apoplexy. Frerichs found that among 250 cases of diabetes, 8 died of nephritis, 10 of cerebral apoplexy, and 2 from cerebral softening. Griesinger found the kidneys diseased in 32 cases out of 64, and Dickinson in 22 cases out of 24.

Such cases, therefore, can be set aside. They may illustrate coma in diabetics, but they are not instances of the diabetic coma, which we are now discussing.

Of the remaining cases, two divisions, according to M. Lecorché (*Archives de Neurologie*), can be made. In the first class, sudden coma comes on without the evidence of acetone in the blood or excretions. The patient falls gradually or suddenly into a state of torpor and great general weakness which ends in coma. The limbs are cool, the pulse feeble, there is no evidence of asphyxia, but the face is pale or even livid. In these cases there is sometimes a hyperglycæmia with desiccation of the tissues, as shown by Abeles, but the dominant factor is cardiac failure from the atrophied and fatty heart.

In the second group of cases there is marked evidence of acetonæmia, as shown by the chloroform-like odor of the breath and urine, and by the Burgundy-red color of the latter when a few drops of perchloride of iron are added. But here the clinical symptoms are entirely different. The patient shows at first evidence of restlessness and excitement. His speech is rapid and vivacious, the pulse quick, the temperature, perhaps, somewhat elevated, and there are in general the signs shown in the first stage of alcoholic intoxication. Besides this, the patient develops gastro-intestinal and respiratory troubles. There is anorexia, vomiting, or diarrhœa, coliky pains. Dyspnœa appears later, of a somewhat peculiar character; the whole chest is deeply and rhythmically expanded, while no physical signs of trouble can be discovered in the lungs.

After the stage of nervous excitement comes stupor, and finally coma.

The cause of the symptoms in this latter group is most likely the acetone or some allied product in the blood. It was Frerichs who believed that it was antecedent decomposition products which were really the toxic agents; yet none of these other substances, such as acid ethyl diacetic, or ethyl ether, injected by Quincke and Gehrardt, seem any more poisonous than acetone, and it is not necessary to assume that a stronger poison than acetone is needed to kill the already weak and debilitated diabetic.

The testimony of most observers, therefore, still supports the view of Petters and Kaulich, that diabetic coma, occurring in the group of cases just described, is due to the presence of acetone or some closely allied body in the blood. And much of the contradiction and confusion regarding the subject is due, no doubt, to the fact that many have supposed that all cases of coma in diabetics were also cases of acetonæmia.

Some important practical points may be mentioned, in conclusion, regarding the influence of treatment upon the development of coma. Pavy and Lasègue have independently stated that severe forms of diabetes, when not treated, died of phthisis; when treated, died of coma.

While this is putting it too positively, there can be little doubt that a sudden reduction in the amount of sugar in the urine by the enforcement of a rigid meat diet may bring on coma. When diabetics have a tendency to acetonæmia, also, they should not be too rigidly restricted to a meat diet, and they should be given opium sparingly.

PRACTICALITY IN MEDICINE.

THE word "practical" has a fascinating sound. It suggests a getting at the bottom of things. But much that passes current as practical is spurious coin. A practice implies a theory, though the latter may not present upon superficial examination. In time past our teaching may have been too theoretical. But the hue and cry of the times is blinding us to the true meaning of the word "practical." In our anxiety about the superstructure, are we not getting careless about the foundation?

A well-ordered education combines both the theoretical and the practical. In our efforts to succeed, we are apt to magnify the latter element and disparage the former. This leads us to strive to reach the goal by short cuts. This spirit has affected our educational institutions. Some of them are merely huge incubators, and their progeny is feeble and dwarfed. In the cold blast of competition only the fittest survive and achieve success. Circumstances have given to this latter word a meaning which it did not possess fifty years ago. How are we to define it? It is certainly not for the great mass of men what it was formerly, so far as pecuniary reward is concerned.

We regard that man as successful in the highest sense who does his own thinking and acts out the convictions to which it leads. This is the highest type of practicality.

If a man can be rightly trained in his habits of thought he will naturally make himself practical. This training must be begun in very childhood. All of our so-called educational reforms have not been unmixed blessings. Every agency which has ever wrought for human good has had in itself the potential for working a vast amount of evil. The good has resulted from a knowledge of the limitations of each agency and its applicability to the wants of men. The liability to evil results from either an endeavor to make, or a willingness to allow, an agency to work contrary to the regular laws of expansion of mind and matter. Over-production in literature has in every profession led to a lessening of individual mental exertion. To a certain extent it has removed one great aid to practicality. A sort of intellectual parasitism has sprung up. Nothing parasitic is ever truly practical. Knowledge gained without sturdy, independent thought is never lasting. We can never employ it with certainty. It cannot be converted into practical endeavor. Functional activity alone prevents mal-assimilation. "The knowledge which we can use is the only true knowledge."

The relation of practicality to independence of thought is thus seen to be very close.

The teachers of the natural sciences in many of our higher institutions of learning complain of a lack, on the part of their students, of originality, and of that mental tone which enables them to stand alone on whatever basis of mental endowment they may profess to have. The student regards the teacher much as a man overboard regards a life-preserver—a sure means of safety. This it is, but it is not a great aid in learning how to swim. The student can throw the blame in part back upon his preparatory school and his previous instructors. Both have suffered to a certain extent from the objective effects of over-production in literature. The many new books produced are in themselves good enough. In fact they are so good, and present their subject-matter in such an attractive form that the student will not go over the premises involved. He contents himself with merely accepting the conclusions. "There can be no doubt," says a recent writer, in speaking of biological studies, "that many teachers take the very books which emphatically urge the necessity of observation and use them just as they would a grammar or history, so that the observation in this case may be said to consist in observing what is said in a certain page of a certain book." The same criticism holds true of many students, and in medical study often leads to the formation of deplorable mental habits.

What, then, is the great guide to practicality? We regard it to be the power of close observation, a studying by each man of those clinical facts which come to his own notice. Experience will eventually show their relation to other facts to which they may seem antagonistic. The cultivation of this power should begin in the earliest student days. The "how" should be regarded as of no less importance than the "what" in considering mental acquirement. He will be the most successful in the true sense who holds, with puritanical sternness, to honesty toward himself as well as toward his fellows.

THE TREATMENT OF RACHITIS BY PHOSPHORUS.

RACHITIS has usually been regarded as a disease dependent upon malnutrition, and, as such, amenable to no specific treatment, but to be managed on general principles by tonic, dietetic, and hygienic measures. Some three years ago, however, at the meeting of German Naturalists and Physicians at Friburg, Kassowitz announced that he had discovered a true specific for rickets, as far, at least, as the osseous manifestations of the disease were concerned. The softening of the bony framework, he maintained, was due to an undue vascularization of the layers of new osseous tissue, the increased activity of the circulation interfering with the normal deposit of calcareous salts. It had been shown by the investigations of Wegner that, when phosphorus in small doses was given to a growing animal, the newly formed bone was very dense, so that the cancellous tissue was as firm and compact as the shaft of the bone. Kassowitz attributed this change to an arrest of development of the young vessels supplying the parts, and he reasoned that the drug would, therefore, be of value in rickets. He accordingly experimented with phosphorus in doses of $\frac{1}{130}$ grain ($\frac{1}{2}$ milligram), and claimed to have obtained most excellent results. He reported over five hundred cases in which he tried the efficacy of phosphorus, in every one of which very marked improvement in all the symptoms followed in the course of a few weeks.

Such a glowing account of the virtues of phosphorus

naturally led others to experiment in the same direction, and since then many reports have appeared from time to time in the journals, some coinciding with those of Kassowitz, and others apparently demonstrating the worthlessness of the drug in this disease.

The question was recently the subject of an animated discussion at a meeting of the Society of Physicians in Vienna (*Centralblatt für Klinische Medicin*, January 30, 1886). It was introduced by Kassowitz, who presented a case of so-called late rickets in a girl ten years of age, in whom an almost complete cure was obtained in a little over two months. Thereupon Hryntschak presented a report of 24 cases of rachitis treated by phosphorus, of which 5 were benefited, 12 remained without change, and 7 grew worse while taking the remedy. Herz, Eisenschitz, and Genser each reported favorably on the action of the drug, having observed an improvement in the general condition, consolidation of the bones, especially those of the cranium, subsidence of abnormal sweating, and cure of laryngismus stridulus.

The principal opponent of this method of treatment was Monti. He said that he had, in certain cases, seen the fontanelles grow smaller during the administration of phosphorus, while at the same time the rachitic changes in the cranial bones were advancing. And even the craniotabes might disappear while the deformity of the thorax was increasing. He doubted very much whether phosphorus exerted any favorable influence upon the laryngeal spasm or upon the eruption of the teeth. He had never seen any improvement in the general condition follow upon the exhibition of phosphorus, except in cases which were placed under good hygienic and dietetic regulations. He was not prepared, however, despite his unsatisfactory experience, to condemn the drug, but was willing to experiment further in the hope of finally seeing more favorable results. The middle ground, and probably the safer one, was taken by Fürth, who believed that phosphorus was a remedy of great value in rachitis, but that it should not be relied upon solely, to the exclusion of measures directed to the improvement of the hygienic and dietetic conditions. He said that the remedy could be given in small doses to children for weeks and months without danger. Some exception must be taken to this statement, however, in view of the fact that Boas (*Berliner klinische Wochenschrift*, No. 25, 1885) has reported two cases of periostitis of the jaw occurring after the exhibition of phosphorus in doses of $\frac{1}{40}$ to $\frac{1}{13}$ grain per diem.

In concluding the discussion Kassowitz referred briefly to his reported cases, over twelve hundred in number, and affirmed his belief that a great revolution in the mode of treatment of rachitis would soon occur. And in order to hasten the coming of this revolution, he begged his colleagues to make a conscientious trial of phosphorus, but cautioned them against impatience; for it was only in exceptional cases that a complete cure could be obtained in a few weeks, although a marked improvement in some or all of the symptoms should be observed in that time.

As far as any judgment can be formed from the many reports that have appeared during the past two years, the weight of testimony would seem to show that phosphorus is a drug of considerable value in the treatment of this disease, though we cannot agree with its most enthusiastic advocates, who look upon it as a true specific. But it certainly ought to be combined with abundant alimentation, for Wegner's experiments have shown that in animals fed with phosphorus, but deprived of phosphates, the newly formed bone, while dense, was not hard, but was precisely like that occurring in rachitis.

DISCUSSING PROPRIETARY MEDICINES.

THE *Philadelphia Medical Times* says: "Dr. Carl Seiler, several months ago, before the Alumni Association of the College of Pharmacy of this city, and within the hall of the college, delivered a lecture upon 'Hay Fever.' . . . In impressing his points upon his audience, speaking extemporaneously, he condemned all powders, and told his audience not to use them. Among the examples which he mentioned was a proprietary article in the form of a snuff, which had been advertised in this city as a 'cure' for hay fever. The professional experience of the lecturer, and his knowledge of the nature of the disease in question, he believed, enabled him to form, and qualified him to express, a positive opinion as to the dangers of a remedy of the kind indicated when used in this highly objectionable manner.

"For this statement, made before a medical audience (for pharmacy is a branch of medicine), Dr. Seiler has been prosecuted by the owner of the nostrum, who claims exemplary damages for injury to his business."

The suit, as our contemporary, the New York *Medical Journal*, truly states, involves the question whether doctors have not a right to discuss freely the value of medicinal agents. If Dr. C. Seiler's case goes against him it follows that medical men and journals will have to keep silent in all therapeutical discussions as to proprietary nostrums.

Surely it will not be for the public good if such a state of things is brought about. No doubt it is unjust for medical men wantonly and maliciously to inveigh against special proprietary preparations, but instances of such action are extremely rare if they ever occur.

The evil effects of the present practice of forcing proprietary mixtures upon the profession and public, have received, in Dr. Seiler's case, a new illustration. We trust that it will be a fresh inducement to the profession to stick to the Pharmacopœia.

SUCCESSFUL LUNG-SURGERY.

THERE is, perhaps, no operation in the whole range of surgery that seems to hold out so little immediate or ultimate success as that of the removal of a malignant growth from the lung. Yet this has been done successfully by Professor Krönlein, of Zurich. The case was one of sarcoma of the chest-wall and left lung, occurring in a woman eighteen years old. The operation was performed in 1884, and its immediate success was chronicled in the *Berliner Klinische Wochenschrift*, No. 9, 1884.

The patient was lost sight of for two years, and it was feared that she was dead. She reappeared, however, a short time ago, and Professor Krönlein states that she is still in blooming health. A careful examination of the lung led to the conclusion that there had been no return of the disease. Cases of sarcoma of the ribs and lung are, of course, extremely rare, but this does not make

Krönlein's contribution to surgery any the less brilliant.

It is impossible not to contrast the striking results of which modern surgery boasts—such as resections of the stomach and intestines, removal of the diseased thyroid, of the larynx, etc.—with the operations upon which our surgical fathers took pride, which were lightning-like amputations, lithotomies, and ligaturing the large arteries. But doubtless our descendants will think with just as pitying smiles of our trivial dabblings in laparotomy and lung resection.

THE INOCULATION OF A CONDEMNED CRIMINAL.

From the Hawaian Islands comes the news of the first attempt to use a condemned criminal for the solution of an important hygienic and scientific question. Over two years ago, the government procured the services of an accomplished bacteriologist and pathologist, Dr. Edward Arning, for the purpose of having a thorough and scientific study made of leprosy. For two years Dr. Arning followed up the subject, and apparently with great industry and skill.

Special attention was, of course, paid to the *Bacillus lepræ*, which was uniformly found in great numbers in the diseased parts, but not in the blood.

Attempts were made to cultivate the bacillus by Koch's method, using various media, but so far Dr. Arning has failed entirely. In this respect, Dr. Neisser, of Breslau, appears to have been more successful, for he has recently stated (*Virchow's Arch.*, 103, Bd. 1886) that in a few cases he has observed an exceedingly slow growth. Neisser also claims to have recognized spores, which Arning, so far, has failed to do. The latter made numerous inoculation experiments upon lower animals. The bacilli would grow at the points of inoculation for a long time, but the animal never became infected.

Finally, by permission of the Privy Council, Dr. Arning was allowed to make an inoculation upon the condemned criminal Keanu, whose sentence was commuted to imprisonment for life. With Keanu's written consent, an inoculation was made of leprous matter in the convict's arm. Bacilli were found in the sore or the scar until fourteen months later, but no constitutional symptoms were observed.

One further observation of importance was made by Arning. He found that in putrid leprous tissues, and even in the body of a leper who had been dead for three months, the bacilli were found in great numbers. This seems to bear against their specific pathogenetic function.

We regret to learn that owing to difficulties with the Health Board, Dr. Arning's work will probably be discontinued.

ALCOHOLISM AND ITS PREVENTION.

A great deal of interest is being taken in France regarding the subject of alcoholism. "This word," says Lanceraux, "was unknown to French physicians previous to 1850, but since that time the pathological phenomena of chronic alcoholic poisoning have been carefully studied." All the French writers agree that the manufacture and sale of alcoholic drinks should be regulated by the State. All seem to agree also in the view, that the most serious physical and moral ills that alcohol produces are the result of using distilled and falsified liquors. Dujardin-Beaumetz and Andige, Lanceraux, M. Girard, and M. Mottet, have given evidence to this effect. M. Mottet cites cases of explosive mania brought on by these adulterated drinks. Lanceraux shows that most of the cases of alcoholism admitted to the Paris hospitals occur in persons brought up in the provinces where brandy is used.

"Children of vinous drunkards," he says, "do not inherit the vice, but the children of parents who indulge in liqueurs and drinks manufactured from cereals and potatoes, show marks of degeneration." He regards wine, beer, and cider as harmless, or only slightly dangerous. But wine must not be fortified (as it usually is) with alcohol.

The French remedy for intemperance is to allow the sale of the weaker liquors above mentioned, but to watch their manufacture and composition. The sale of distilled liquors should be carried on by only a few responsible persons; these liquors should be heavily taxed, and the most stringent regulations should be made to prevent their adulteration, and secure their careful manufacture.

THE "CRAMMING METHOD" IN PHTHISIS.

Many observers, in this country and elsewhere, have attested to the therapeutic value of the method of "cramming" in phthisis. It has not been found necessary in all cases to use the syphon-tube, although that is usually a most effective help.

Quite recently some interesting observations upon this subject have been made by Dr. M. G. Kurloff, of St. Petersburg. He made six experiments upon five phthisical patients who had been rapidly emaciating. These patients were given a mixture of milk and meat-powder, nearly a pound of the latter being given at a time. The average amount of nitrogenous food daily was equivalent to $3\frac{1}{3}$ pounds of fresh meat, while the maximum was equal to $5\frac{1}{3}$ pounds of fresh meat. The average amount of nitrogen ingested daily in this mass of food was from 50 to 80 grammes, against the average, in an ordinary diet, of 18 grammes.

The effect of this cramming was to increase greatly the excretion of nitrogen (not necessarily the tissue-waste, as Kurloff states). Thus the nitrogen excreted by the urine rose from a mean of twelve grammes daily to thirty-four and fifty-six grammes.

Of more importance was the fact that the nitrogen assimilated was increased, or, in other words, tissue was built up at a rapid rate. Thus the mean assimilation, expressed in grammes, per kilogramme of body-weight before, during, and after the cramming process, was respectively 0.24, 0.89, and 0.29. The patients' appetites improved, and the body-weight increased at the rate of nearly one pound a day. The treatment was, however, kept up for too short a time to obtain anything but experimental results.

These confirm previous experience as to the value of the cramming process, and point especially to the need of genuine cramming, *i.e.*, of giving food in very large excess.

News of the Week.

A Duel among Doctors.—The editor of the *American Practitioner and News* appears to have had a genuine challenge to fight a duel. This must be an agreeable change from the hard routine of the medical editor's life, and we trust our esteemed contemporary is enjoying it. The "challenger" is at present an individual who wrote a ridiculous tirade for the *News*, and sent it anonymously. The *News* printed some specimen imbecilities, and concluded by saying: "The communication is anonymous, and it is well for the writer that it is so." Whereupon the writer pens the following: "If you feel that you would like to have any sort of personal satisfaction from the writer, and can furnish a respectable indorser to that effect, my name shall be forthcoming." We may yet have some gunshot surgery in Louisville.

The European Medical Press.—For unblushing misrepresentation we imagine that nothing can much exceed a statement in *The Medical Bulletin*, to the effect that the present organization of the Congress "receives the earnest support of *The British Medical Journal*, *Le Progrès Médical* (not *Medicale*), and other influential European journals." We are furthermore told that the *Medical Times and Gazette* had to suspend because it attacked the American Medical Association! It is a bad case when such trumpery statements have to be brought in to its support. They only promote bad feeling, and make concessions and settlement more difficult. The fact is, that there is not a European medical journal, except perhaps two, which is not in a quandary over the Congress.

A New Reason for Banishing the Classics.—Professor Theophilus Parvin, in a recent eloquent and learned lecture, said: "It is sadly true that the study of the classics is calculated to breed and foster immorality. Virgil, in immortally beautiful language, really makes arguments in favor of onanism and pæderasty. If for no other reason, for this alone, I would favor the banishment of the classics from college courses, for they have a tendency to sow that terrible seed about which I have spoken." We can hardly believe that Professor Parvin is serious in the above statement. There is certainly nothing worse in the best classic writers than in the best English classics, while one modern French novel can outdo the whole Augustan age in nastiness. As for Virgil, we cannot have him slandered so. From a pretty thorough knowledge of what is medical, at least in Virgil, we recall only one passage that at all appears to "encourage immorality." This amounts to not much more than Tennyson's

"In the spring the young man's fancy lightly turns to thoughts of love."

Virgil, says Horace, was the best of men and of friends.

The American Analyst makes the charge that The Medical Record has "attacked" the cigarette-makers of a certain Richmond firm, and has accused them of immorality, etc. Our astute critic is quite mistaken, as he would see if he had read the article in question more carefully. What we did say was that working-women who pull up their dresses when being photographed for the public, are presumably of loose character. We advise our contemporary not to press this discussion.

The Arkansas State Medical Society will meet at Helena on April 28th.

Another Point of View.—"If we might express our own observations, we would suggest that a thorough education is one of the least factors in the elements which go to make the practice of medicine successful from a monetary point of view; and we fail to see how any profession could be attractive to thoroughly educated young men in which success, in its usual acceptation, bears no ratio to learning and proficiency."—*Miss. Valley Med. Monthly.*

The Medical Practice Act of Illinois has accomplished the following in its eight years of existence: In 1877 there were 7,400 persons engaged in practice, of whom 3,600 were graduates, and 3,800 non-graduates. In 1886 the total number engaged in practice was 6,065, the graduates being 5,327, the non-graduates 738. The effect of the law has been, therefore, to keep down an increase in doctors and to reduce the proportion of non-graduates from fifty-two per cent. to thirteen per cent. Assuming that the population has increased by several hundred thousands, it would be a fair estimate to suppose that the proportion of physicians to population in Illinois is not far from 1 to 600. In the neighboring State of Indiana it is 1 to 396, and in Ohio 1 to 500.

The Louisville Medical College graduated a class of eighty-seven at its Annual Commencement, February 25th.

Two Newspapers and a Moral.—We have received two newspapers, one a German daily, published in St. Louis, and the other *The Kansas City Journal*. One contains the woodcut and glowing biography of a gentleman somewhat known in gynecological circles, and hitherto standing well in the profession; the other, published in much the same style, is evidently that of a confessed quack. There used to be a geometrical axiom to the effect that "two things equal to the same thing are equal to each other." Does it apply here?

Bad Water and Typhoid in Philadelphia.—At a meeting of the County Medical Society, held in Philadelphia on March 24th, a resolution was passed advocating the completion of the East Park and Cambria reservoirs. Dr. Thomas said that Philadelphia water is contaminated by sewer water and cemetery leakings. Many ladies would not drink the water, and many diseases were caused by too little water drinking. The water is no longer fit for domestic uses. There is more typhoid fever in Philadelphia than in any city of its size in the world. —*Sanitary News.*

More "Successful" Treatment of Diphtheria.—Dr. H. Heyder, of Plau, in Thuringen, states in the *Centralblatt für Klin. Med.*, 1886, No. 12, that he has treated two hundred and fifty cases of pure diphtheria, in the past two and a half years, with a mortality of only seven, or two per cent. He has uniformly used chlorate of potash and muriatic acid, giving these drugs alternately. To older persons he gave also a gargle of corrosive sublimate (1–3,000), to babies he gave a solution of the salt.

Trichinæ have been found in wild hogs by the persons at Potsdam engaged in examining their flesh.

A State Charities Aid Association has been organized in New Jersey.

The Annual Meeting of The Medical Association of Georgia will be held in Augusta, on April 22, and 23.

A Polyclinic is to be organized in Atlanta, Ga. Commenting upon this the *Atlanta Medical and Surgical Journal* speaks of the "Polyclinic in Vienna." There is no "Polyclinic" in Vienna, but there is a Policlinic.

The French Government has passed a law permitting persons to make a will giving their bodies to learned societies.

Sir Henry Thompson has written a new novel entitled "All But." He has illustrated it himself with numerous sketches.

The Death of Professor C. C. F. Gay, a well-known surgeon of Buffalo, is announced. Dr. Gay was Professor Emeritus of Operative and Clinical Surgery in the Niagara Medical College.

Double Cataract Extraction at an Advanced Age.—An old Russian tailor whose age is one hundred and one has just had cataract extraction performed successfully on both eyes.

Medical Books in Germany.—There were nine hundred and four medical works issued by German publishers in 1885, as against nine hundred and twenty-eight in 1884.

Professor Billroth, of Vienna, accompanied by one of his assistants, recently went to Alexandria, Egypt, to perform an operation upon the person of a rich banker there. For the expenses incurred and his services he was to receive the sum of 25,000 francs.

A Pasteur Institute in Russia.—Prince Alexander of Oldenburg has created, at St. Petersburg, an establishment on a small scale for applying Pasteur's method. Experiments are made on dogs and rabbits before operating on man. Prince Alexander defrays all the expenses of the establishment.

Beri-beri is ravaging the whole coast line of Brazil, and is causing a greater mortality than yellow fever. Beri-beri in Brazil, according to a correspondent of the *Journal of the American Medical Association*, is widely different from the disease of the same name in India. The Brazilians do not seem to know its true nature, viz., that of a multiple neuritis.

A Novel Operation in Liver Surgery has been performed by Dr. George Harley (*Med. Press*). In a case of acute hepatitis with enlarged liver, ascites, and other symptoms pointing to an inevitable fatal termination, Dr. Harley introduced a trocar and cannula deep into the centre of the liver and drew off twenty ounces of blood. The patient made a good recovery, and Dr. Harley thinks that hepatic phlebotomy is destined to take rank in therapeutics as a safe and effective measure.

Reversion of the Blood to a Lower Type.—Dr. Frederick P. Henry, of the *Philadelphia Medical Times* advances the theory that in pernicious anæmia there is a reversion of the blood to a simpler ancestral type. He finds that the blood-corpuscles in this disease are reduced to half a million or a million per cubic millimetre; that the proportion of hæmoglobin is often increased above normal; that many of the corpuscles are greatly increased in size and are altered in shape, being oval. In all these respects the blood approaches, as he believes, the character of that of cold-blooded animals. Dr. Henry calls it a case of "tissue reversion;" but blood is not now generally regarded as a tissue but as an internal medium. We fear that the hypothesis of Dr. Henry must be considered somewhat fanciful.

Dr. A. M. Shew, Superintendent of the Connecticut Hospital for the Insane at Middletown, was stricken with apoplexy on April 12th, and died on the same day. His health had not been good for several years, and much of the time he had been absent from his duties. He was born in Jefferson County, N. Y., September 18, 1841. In 1862 he accepted the office of Assistant Physician in the New York Asylum for Insane Convicts, at Auburn, after which he went to Philadelphia and graduated at the Jefferson Medical College. Later he became Assistant Surgeon of United States Volunteers. In the spring of 1866 he was appointed Assistant Physician of the New Jersey State Lunatic Asylum at Trenton, and remained there until the following September, when he was appointed to superintend the construction and organization of the Middletown Hospital.

New Medical Societies in Russia.—Two new medical societies have recently been started in Russia. One is for the study of syphilis and dermatology, and has already met several times, the president being Professor B. Tarnovski, and the vice-president Professor Polotebnoff. The other, devoted to ophthalmology, is in process of formation.

American Public Health Association.—The Executive Committee have selected the following topics for consideration at the next meeting of this Association, which will be held at Toronto, Canada, October 5 to 8, 1886: 1. The Disposal of the Refuse Matters of Cities and Towns. 2. The Condition of Stored Water-Supplies, and their Relation to the Public Health. 3. The Best Methods and the Apparatus Necessary for the Teaching of Hygiene in the Public Schools, as well as the Means for Securing Uniformity in such Instruction. 4. Recent Sanitary Experiences in Connection with the Exclusion and Suppression of Epidemic Disease. 5. The Sanitary Conditions and Necessities of School-houses and School-life. 6. The Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the Best Means and Appliances for Preventing and Avoiding Them. 7. Plans for Dwelling-Houses.

Poisoning from the External Application of Aconite.—We have received some communications which make it doubtful whether the case of supposed poisoning by the external application of aconite, reported in The Record of February 27th, page 243, was really one of that character. It is certainly very unusual for tinct. aconite to be absorbed by the skin.

A Ready Method of Making Koumiss.—Take one square cake of compressed yeast, dissolved in a tumbler of warm water, a dozen cubes of sugar, and two quarts of milk; then put all in patent beer bottles; let it stand twenty-four hours, [illegible]

Reviews and Notices.

Rome in Winter, and the Tuscan Hills in Summer. A Contribution to the Climate of Italy. By David Young. Pp. 283. London: H. K. Lewis. 1886.

This book describes the principal elements in the climate of Italy: "The prevailing diseases are compared with those of England and northern countries generally, and the *type* of diseases likely to receive benefit in Italy is dwelt on at some length, while the sanitary state of the city" [of Rome] "and the important and increasingly interesting subject of malaria are also considered." The author considers the subject of climate generally, and that of Rome in particular, in the first two chapters; in the third and fourth chapters he discusses the unhealthiness of Rome and Roman fever. There is a very interesting chapter on "The Water-Supply of the City," both ancient and modern, and one on "How to live in Rome." The description of "Summer Quarters near Rome and in Tuscany" are of special interest, and embrace two chapters. The ninth chapter is devoted to "The Class of Invalids likely to derive Benefit from a Residence in Rome." A feature of interest is the description of the so-called "Roman fever." This disease is compared to the "typho-malarial" fever which so generally affected raw soldiers during the War of the Rebellion. It would appear that Roman fever is a sickness due to exposure to thermal vicissitudes during nervous exhaustion; thus "Some, after a shorter or longer period devoted to sight-seeing in Rome or Naples, began to feel fatigued and ill, this condition being soon followed by an attack of diarrhœa. Others attributed their illness to a chill caught on their return homeward about sunset." The author claims a malarial influence as causative, but thinks the disease more akin to typhoid than any other fever. The fever is not liable to recur. There seems to be three principal theories in respect to the origin of "malaria" in Italy: "(*a*) That the disease is produced by weather influences alone; (*b*) that it is due entirely to the soil; and (*c*) that it is essentially a disease of parasitic character." A great deal of space is taken up with a discussion of this subject, but the reader is left in the same state of doubt that has always existed in respect to the character of malaria; perhaps it would be well to banish from medical nomenclature a term used to obscure rather than clear up the causes of much of the illness to which mankind is subject. The "evil one" of theological form has scarcely served to create more illogical disputation than has "malaria." The author gives much information of value to both physician and tourist.

The Adirondacks as a Health-Resort: Showing the Benefit to be derived from a Sojourn in the Wilderness in Cases of Pulmonary Phthisis, Acute and Chronic Bronchitis, Asthma, "Hay-Fever," and various Nervous Affections. Edited and compiled by Joseph W. Stickler, M.S., M.D., Visiting Physician and Pathologist to the Orange (N. J.) Memorial Hospital, Member of the New York Pathological Society, etc. Pp. 198. New York and London: G. P. Putnam's Sons. 1886.

In view of the somewhat chaotic and unsatisfactory condition in which we find the literature pertaining to the New York wilderness as a resort for invalids, it is a matter of congratulation that so competent an investigator as Dr. Stickler has taken the trouble to make a careful study of the subject, and to bestow upon us the benefits of his labors in the little volume which lies before us.

Chapter I. treats of the importance of climatic treatment in pulmonary affections, chiefly by quotations from acknowledged authorities on the subject. The author then briefly describes (Chapter II.) the chief localities of interest to physicians and invalids in the Adirondack region, the methods of access to them, their altitudes, variations in temperature, etc. Chapter III. treats of "Camping," and contains some useful hints regarding this (in many cases) valuable adjunct to a sojourn in the mountains. The remainder of the book is taken up with communications to the editor from physicians, clergymen, and others who have had personal experience in the woods. Among the medical contributors are Drs. Loomis and Leaming, of New York; Levick, of Philadelphia; and Ward, of Albany. A striking unanimity of opinion in favor of the climate of the Adirondacks for many forms of disease is observed in the correspondence. Indeed, a superabundant enthusiasm leads several of the contributors to draw rather heavily on the credulity of their readers. For example, the statement on page 48, by a distinguished Boston divine, to the effect that the water in some localities is so lucid that a newspaper might be read through eight or ten feet of it in a perfect calm! Barring these occasional overflows, the book is to be highly commended, and merits a careful perusal, not alone from invalids contemplating a change of climate, but from every progressive practitioner of medicine as well. The contributions of Drs. Loomis and Levick are especially worthy of attention. A map of the region would enhance the practical value of the book.

The Methods of Bacteriological Investigation. By Dr. Ferdinand Hueppe, Docent in Hygiene and Bacteriology in the Chemical Laboratory of R. Fresenius, at Wiesbaden. Translated by Herman M. Biggs, M.D., Instructor in the Carnegie Laboratory, and assistant to the Chair of Pathological Anatomy in Bellevue Hospital Medical College. Illustrated by thirty-one woodcuts. New York: D. Appleton & Co. 1886.

The study of bacteriology is one which at the present day is of exceeding importance, but which in this country has hitherto been pursued by but a very few even of the younger generation of physicians. One great cause of this neglect has been the want of a suitable manual of instruction in the method of bacteriological investigation. Another has been the lack of instructors and of institutions in which the rudiments at least of the science might be taught. The latter want has been supplied in a measure in the large medical centres, and now the former, without which the latter would be incomplete, has been met in a most satisfactory manner by the work before us. Dr. Hueppe needs no introduction to those who have any acquaintance with the literature, already so voluminous, of this new and fascinating branch of medical science. The work treats in a most thorough and comprehensive manner of the whole subject of bacteriological study, and includes a description of the different forms of bacteria, the manner of isolating them by culture, the methods of staining, etc. A brief notice is given of the process of inoculation for the determination of the etiological relation of bacterial growth to disease, and also of the methods of investigation employed to ascertain the presence of micro-organisms in the earth, air, and water. The translation is well made, and illustrations are inserted wherever they are necessary to make the text more clear. We can commend the book to all who desire to acquire a general knowledge of the subject of bacterial pathology, even though they may not have the opportunity or the inclination to study the question practically. To those who wish to have more than a mere theoretical knowledge of the subject, the manual will be found to be indispensable.

"One Hundred Doses for a Dollar," is the way a patent medicine heads its "ad." Man takes a dollar's worth. Then the undertaker comes along, and it costs the man one hundred dollars for one dose. Thus we see all things come around even in this old world, after all.—*Burdette.*

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 24, 1886.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. G. C. FREEBORN, from the Committee on Microscopy, reported that the tumor of the brain presented in behalf of a candidate at the last stated meeting was a *small, round-celled sarcoma.*

DR. H. MARION SIMS presented, in behalf of a candidate, a specimen of *dermoid cyst and carcinoma* in the same ovary, accompanied by a microscopic section.

DR. GEORGE F. SHRADY presented, in behalf of a candidate, specimens removed from the body of a child that died of *acute miliary tuberculosis.*

DR. T. MITCHELL PRUDDEN presented, in behalf of a candidate, a specimen of *intussusception.*

DR. L. WALDSTEIN presented a specimen which showed

STRANGULATION OF THE JEJUNUM BY A DIVERTICULUM.

The patient was admitted to the German Hospital with symptoms of perforative peritonitis. The autopsy revealed a loop of the jejunum cyanosed and filled with bloody liquid, constricted under a diverticulum from the ileum which had become adherent lower down as the result of an old inflammatory process. He had presented two similar specimens within a year.

Dr. Waldstein also presented a specimen which illustrated

ELONGATION AND ABNORMAL FIXATION OF THE VERMIFORM APPENDIX,

attended by perforative peritonitis. It was removed from the body of a child nine years of age, who died after an illness of five days. The specimen confirmed an opinion expressed at a former meeting, that fixation of the vermiform appendix in abnormal positions by adhesions was favorable to the development of typhlitis. In this specimen there was evidence of chronic inflammation involving the mucous membrane, followed by acute inflammation and perforation.

Dr. Waldstein also presented a specimen of

FIBROMA OF THE MESENTERY,

removed from the body of a woman thirty-one years of age, who was never specially sick, although anæmic in girlhood, whose menstruation was regular, painful in the beginning, and who was the mother of three children, all the labors being normal. In 1884 she aborted at the fourth or fifth month. Since the spring of 1885 she had suffered from constant pain in the abdomen, but it was especially severe after exertion. Since November last pain has occurred in paroxysms, extending to the small of the back, down the thighs, and, on account of vomiting, she supposed herself to be pregnant. Menstruation ceased. She also began to emaciate. The bowels were usually regular. Occasionally there was discomfort in urinating.

When admitted to the hospital, January 10, 1886, she was pale and somewhat emaciated, with a temperature of 99.3° F., and pulse of 100. In the median line, from the symphysis pubis to nearly the umbilicus, there was dulness on percussion, and pressure in this region elicited pain. A little to the right of the median line, when the patient was lying upon her right side, a tumor could be felt distinctly, which was adherent to the abdominal walls. The patient was anæsthetized, when it was found that the tumor could be easily moved over to the right side of the abdomen, but not to the left, and even up to the lower edge of the liver, while the uterus remained in its normal position, and the tumor had no connection with the ovary. The left kidney could be felt, but the right one could not be recognized. The tumor seemed to be ovoid in shape, and the diagnosis of movable kidney was made.

The patient died on January 22, 1886, with symptoms of perforative peritonitis.

The autopsy revealed a dilated and cyanosed small intestine, with bloody serum in the pelvis. To the right of the umbilicus there was an oval tumor, hard, and measuring twelve centimetres long, eleven wide, and ten thick, which carried the jejunum with it when moved; but on close examination it was found that it was situated between the folds of the mesentery, which accounted for its close proximity to the intestine. The vessels of the tumor were large and distended, and in several places there were extravasations of blood.

Microscopical examination of the tumor showed that it was a pure fibroma. There was no enlargement of the lymphatic glands.

DR. J. C. PETERS said that Dr. Alonzo Clark had reported a case of tumors connected with the intestines, which were decided to be adipose rather than fibrous; there were several, and some of them had become detached and were loose in the peritoneal cavity.

DR. MENDELSON asked Dr. Waldstein if the tumor he presented was a true fibroma, or was it a myo-fibroma? showing that it may have originated in the muscular coat of the intestine.

DR. WALDSTEIN replied that he examined carefully with reference to the presence of muscular tissue, but was unable to find any; and he also examined with reference to the condition of the lymphatic glands in the region of the tumor, but had no reason to suppose that it originated in this kind of tissue.

ABNORMALITY OF THE PLACENTA.

DR. H. J. BOLDT presented a placenta which showed an abnormality that he had been unable to find reported. There was a peculiar corrugation of the fetal surface leaving it 11 c.c. in diameter, while the maternal surface was 15 c.c. in diameter. The fetal side showed an unusual vascularity and a number of small cysts. On the margin of the fetal surface there was a hard rim from which the three layers of membrane sprang, and in the middle portion of it there was also a layer of apparently fibrous tissue which encircled that side of the organ. The cord exhibited the same varicosity seen upon the placenta, and a fold of the amnion had been thrown of and become attached to the cord at a point situated at a considerable distance from the placenta. The labor was normal, and the pregnancy one which followed immediately on recovery from an attack of septicæmia. The specimen was referred to the Committee on Microscopy.

Dr. Boldt also presented specimens taken from the body of a child five months old that died with symptoms of

TUBERCULAR MENINGITIS.

It was said to have been well up to March 6th, with the exception of a suppurating eczema behind the ears, which then ceased to suppurate and healed quickly. The symptoms were such as at first to lead both the attending physician and Dr. Boldt to the diagnosis of bronchial catarrh. Afterward the child was found rather sluggish and having had a number of attacks of vomiting and some diarrhœa. Dr. Boldt made the diagnosis of tubercular meningitis, which was confirmed by Dr. Janeway. At no time did the child's temperature rise more than one degree above the normal.

At the autopsy the pia mater was found injected with blood, but free from tubercles. The lateral ventricles were distended with serous fluid, and their walls were soft, as was also the entire central portion of the brain. At the base of the brain and in the fissure of Sylvius only were tubercles found. The lungs showed only a few tubercles. The bronchial glands were enlarged, as also

were the mesenteric somewhat. The other organs were normal.

Dr. Peters asked Dr. Boldt whether the drying up of the suppurating processes had anything to do with the internal disease, or was it rather that the severity of the internal disease had caused it to disappear.

Dr. Boldt thought that the latter was more probable than the former.

Dr. T. Mitchell Prudden presented a specimen of

ANEURISM OF THE HEART, WITH CHRONIC ENDOCARDITIS AND MYOCARDITIS FROM CHRONIC INFLAMMATION OF THE CORONARY ARTERIES.

He was indebted for the clinical history of the case to Dr. Lambert, of Bellevue Hospital.

The patient was a married German cigar-maker, aged fifty-five. On admission he was unable to talk, but it was learned by signs that he had been sick for two months; in what way he could not explain. Two days before admission he was suddenly attacked with aphasia and paralysis of the right arm and leg. During the twenty-four hours preceding his admission to hospital his aphasia and paralysis had somewhat diminished.

On admission, March 20th, the temperature was 99° F. There was paralysis of the right side of the face, and partial paralysis of the right arm and leg. He could walk with assistance, but could not use the hand at all. He could feebly move the muscles controlling the elbow and wrist. His articulation was thick, and there were many words which he could not utter. He could write backward with his left hand (mirror-writing). He had well-marked Cheyne-Stokes respiration. Urine: Amber-colored; acid; sp. gr. 1026; fifteen per cent. albumin.

Physical examination.—Heart: A double murmur of the usual quality of a friction sound was heard at the apex. Apex beat displaced or diffuse. Heart's action regular. Lungs: Flat over both sides; behind there were subcrepitant râles. Tongue déviates to right. On the following day there were four loose movements of the bowels, and the heart-beats were feebler. He died on the third day after admission.

Autopsy.—Twelve hours after death. Brain: Meninges and brain-substance very œdematous. Patches of atheroma in all the large arteries at the base, particularly those of the middle cerebral and basilar. There was no hemorrhage, and no evidence of embolus. The abdominal visceræ were bound together by abundant loose old adhesions. About six hundred cubic centimetres of fluid in each pleural cavity. Pericardial sac contained about fifty cubic centimetres of fluid. The heart was large and extended toward the left. Both ventricles were widely dilated and their walls considerably hypertrophied. Both auricles were dilated. The pulmonary and tricuspid valves were slightly thickened. The aortic and mitral valves were somewhat thickened, and the latter presented numerous large patches of fatty degeneration. The lower right anterior third of the left ventricle was pouched outward about three centimetres, forming a broad ovoidal pocket about ten centimetres long and four centimetres wide. The wall of this pouch—*i.e.*, the heart-wall—at the thinnest point, which was just to the right of the apex, was about two millimetres thick, and composed almost entirely of dense connective tissue, which enclosed a few atrophied bundles of muscle-fibre. Over about one-third of the pouch the wall was nearly five millimetres in thickness, and from this it gradually thickened toward the sides, until it merged into the hypertrophied ventricle-wall, which, in its thickest part, measured about twenty millimetres. The endocardium lining of this aneurismal pouch was much thickened, and in places fatty and calcified. There were no adherent clots in the pouch. The endocardium of the left ventricle was everywhere moderately thickened. A large red clot lay against the papillary muscles in the cavity of the ventricle, and very voluminous red and white clots were entangled among the muscles. These clots showed very well ribs and striæ upon their surfaces, caused by the heart's movement. The larger trunks of the coronary arteries showed numerous layers and smaller patches of chronic endarteritis, some of which had encroached considerably upon the lumen of the vessels. This was most marked in the trunk leading to the pouched region. The aorta throughout its entire extent was the seat of numerous larger and smaller patches of fatty degeneration and atheroma. The radial artery was also thickened. Lungs: Slight adhesions of right lung behind. Both were congested and œdematous. Spleen: Slightly enlarged; very dark in color, and hard. Kidneys: Slightly enlarged; capsule free. Kidney-substance very dark red in color, dense, and hard. Liver: Showed dilatation of the central veins of the lobules. Microscopically, the kidneys showed the lesions of chronic congestion. There was no thickening of the walls of the blood-vessels.

The President presented a mounted specimen, prepared by Dr. J. S. Thatcher, from an

INFLAMED MOLE OF THE FACE,

which he removed by operation from a lady thirty-four years of age, the mother of two children, the last six or eight months old, that had scratched and irritated this growth until there was marked thickening of the skin about it, and of the tissues underlying it, and the patient became alarmed because of the existence of cancer in the family—an aunt and grandmother having died of that disease. Dr. Wyeth removed the nodule, with the skin to the distance of half an inch surrounding it, and carried the incision down to the lower jaw and entered the corner of the mouth. Microscopical examination showed the thickened tissue was made up largely of embryonic tissue with giant-cells belonging to the benign process of inflammation. The surgical point in the case was, that such benign growths under irritation might become malignant.

The President also presented a specimen of

MYXOMA OF THE BREAST,

removed from a patient thirty-eight years of age, who had never been pregnant. The tumor had a history of six months' duration, and began in the inferior portion of the left breast. Of late it had been exceedingly painful. It was an inch by an inch and a half in area. The entire breast was removed, and the axillary space was explored, although there was no external evidence of enlargement of the axillary glands. The surgical point was, that with all tumors of the breast, whether malignant or not, of six months' duration, exploration of the axilla should be made to determine whether or not there exists any secondary affection of the glands, and if so, to remove them at once.

The President also presented a mounted specimen of

FIBRO-MYOMA,

removed from the left side of the tendo Achillis. It was of two years' duration, had been intensely painful, and was about as large as the end of his little finger. No nerve-filaments were detected in the mass.

Dr. Carpenter asked Dr. Wyeth if he still adhered to his former statement that there was no sarcoma without giant-cells, and if so, could it be reasonably inferred that the presence of giant-cells in a growth of the character just reported indicated the presence of sarcoma.

Dr. Wyeth said that when he made the statement in the Society, a year or so ago, he based it upon the authority of Cornil and Ranvier. He would not, because of the presence of giant-cells, regard a specimen as necessarily sarcomatous.

Dr. Carpenter remarked that he did not accept either proposition.

Dr. Prudden said that the statement that sarcoma did not occur without giant-cells could not be sustained.

Dr. Waldstein had very often found giant-cells in tissues which were in the state of chronic inflammation, and also had frequently found them where they were evi-

dently developed in connection with degeneration of striated muscle-fibres; also associated with diseased glandular structure, where they possessed no special significance. In the growth excised by Dr. Wyeth both striated muscle-fibres and sebaceous glands were involved.

At the stated meeting, January 13th, Dr. A. Jacobi presented, in behalf of Dr. Willy Meyer, a specimen of

SUPERNUMERARY MAMMA,

with the following history, which, on account of the rarity of the specimen, the Society voted that it be printed with proceedings, together with the discussion.

"On October 6th of last year, I extirpated from the left axilla of a woman, twenty-seven years of age, a tumor, the clinical and microscopical appearance of which were of some interest.

"Mrs. Ph. F——, of this city, a healthy though delicate-looking person, passed three pregnancies. During the five months before her last confinement she noticed a small tumor in her left axilla, which gave rise to a slight pain now and then, but caused no other inconvenience. It grew slowly but steadily. In the middle of September she was confined of a healthy baby. A few days afterward she found a small tumor of the size of a walnut in her left breast, with more pain than that ever caused by the one in the left axilla. This gave her a good deal of mental trouble, as her mother had died of cancer of the breast.

"As soon as she was able to walk, she therefore consulted Dr. A. Jacobi, who did not think much of the last-mentioned tumor, but advised the extirpation of that in the left axilla, and sent her to me for that purpose.

"On examination I found in the axilla an oval, rather hard, flat tumor, with an uneven surface, firmly attached to, and movable with, the skin, which was folded over it, the folds running in all directions. By palpation it consisted apparently of several connected parts of an acinous structure, the touch of it being very similar to that of a lipoma. Pressure not painful. A broad but thin and smooth pedicle (fascia) led to the depth of the axillary cavity. No round strings could be felt in it. Around it were many swollen, soft axillary glands. A little above the exterior upper quadrant of the left breast was the above-mentioned tumor, apparently a small so called 'mamma aberrata' seu 'accessoria.'

"According to this condition, it seemed rather impossible to make a positive diagnosis.

"The diagnosis of lipoma was excluded, on the ground that the tumor was too hard and too firmly attached to the 'folded' skin, and had grown too quick to its present size, although it was possible that the patient did not pay any attention to it when in its first development.

"For a fibro-sarcoma of the skin the tumor's fat-development under the skin, and the unchanged though folded surface of it, was strange.

"For a 'cancer' of the skin the patient seemed too young.

"The most probable diagnosis was 'supernumerary mamma' (aberrata). But then it seemed rather curious that this scattered tissue had displayed its physiological character only in the course of the third pregnancy.

"On account of the uncertainty of the diagnosis, and the anxiety of the patient, the removal of the tumor seemed most advisable.

"On October 6th I performed the operation, which required a thorough preparation of the whole axillary cavity—as the broad pedicle was a continuance of the deep pectoral fascia—and consisted in the removal of all the contents of the cavity and a portion of the skin. The diagnosis, supposed to be the right one, became evident in the course of the operation, when, by a superficial incision into the tumor, a white fluid mixed with serum (milk) escaped. (Of course it had to be proved by the microscope that it was not 'cancer'-juice.)

"The operation, performed antiseptically, had the usual good results. The wound healed by first intention, under the first dressing, up to the spot where a small drainage-tube led to the depth of the axilla. The tube was removed at the first change of the dressing (fifth day post operat.), and union was perfect ten days later. During this time the smaller node in the left breast had almost entirely disappeared, as I had assured the patient it would do.

"*Microscopical appearance.*—Dr. L. Waldstein was kind enough to examine the tumor and the glands microscopically. The tumor was evidently an adenoma, as it showed plainly acini and milk-ducts such as are seen in the mammary glands. The epithelial cells covering the inner surface of the acini and the ducts, as well as their ramifications, were more or less enlarged and showed a granulated protoplasm (production of milk). In many spots they were very numerous, reminding one of the nests of epithelial cells in cancer. But these nests evidently did not send the characteristic prolongations into the adjoining connective tissue; they only filled the lumen of the ducts. Besides, there was not the more or less dense infiltration of the connective tissue with smaller round cells, as is usually found in cancer. Nevertheless it seemed necessary, to clear up this part of the diagnosis, to examine the lymphatic glands which had been extirpated also. These showed the signs of the irritation only originating from the lactation process—'enlarged follicles and dilatations of the lymph-sinuses.' The epithelial cells which were discovered here and there showed the same granulated protoplasma as those seen in the tumor, and were carried away from there by the lymph-vessels.

"After all this, it is evident that the tumor represented an 'adenoma' consisting of normal breast-tissue. It belongs to the class of the 'supernumerary mammary glands,' as they are not so very infrequently found—but with a mammilla—on the lower and inner side of the normal mamma or in the axilla, more rarely in the median line of the abdomen, on the acromion, on the thigh.

"Certainly removal of the tumor was indicated, even with this benignant character. For it is a well-known fact that cancer of the breast likes to take its origin from these 'partes aberratæ,' a circumstance still more important in regard of the hereditary predisposition existing. Proper attention is therefore to be paid in this case to the above-mentioned, now scarcely observable, smaller tumor in the left breast. Should it grow in later years, its early removal is advisable."

Dr. A. G. Gerster remarked that supernumerary mammæ in the vicinity of the axillary cavity were more common than was usually believed, and during lactation they can be felt very frequently, especially in thin women. They are detached bodies which become distended, but may be connected with the mammary gland by lacteal ducts which terminate in a nipple. As many as four or five of these bodies have been found in the axillary cavity with a common excretory duct.

Another fact is that these detached bodies of mammary tissue sometimes become the seat of carcinoma. Dr. Waldstein had examined a specimen for him, and found that the carcinomatous growth commenced in one of these bodies situated close to the axillary cavity. Under such circumstances, of course, the mammary gland proper becomes involved first in the part nearest to the detached body.

Dr. Jacobi said that Dr. Gerster's remarks made the case which he had presented still more remarkable. First, the woman was rather thin; second, she did not have a large mamma; and, third, she had not noticed anything at all after the first and second pregnancies, and it was only in the third that this tumor made its appearance.

Dr. Waldstein remarked that supernumerary mammæ were not at all rare, and were found over the thorax, but they nearly always had nipples of their own. It seemed remarkable in the specimen presented by Dr. Jacobi

that there was no such excretory duct connected with it. In addition to what Dr. Jacobi had said, he would take the liberty of adding that some of the axillary glands were also examined in this case, and they showed simple intumescence; besides, it was interesting to notice that colostrum was found in these enlarged glands. The connection between the supernumerary gland and the mammary gland proper could not be found, which made it additionally interesting, because the milk was obliged to seek an outlet through the lymphatic system.

Correspondence.

DETERMINATION OF THE SEXES.

To the Editor of The Medical Record.

Sir: Having read much that has been written of late years in the current medical literature on the "Influences that Determine the Sex of Infants," I have reached some conclusions which may, perhaps, merit discussion in your journal.

The contribution of Dr. Charles Ambrook, in The Medical Record for January 16, 1886, is particularly interesting, as it attempts a solution of the question by references to the lower organisms. Observations on the mating of cattle, dogs, rabbits, and other domesticated animals, though carefully tabulated for many years, have added nothing to our knowledge on the subject. To eliminate all disturbing factors from the question, we must commence by a study of the lower organisms, where growth and reproduction are the sole functions of existence, applying our deductions afterward to the condition influencing the higher forms, for our theory must be broad enough to cover every form of life.

From a study of the lower organisms, as well as from the rudimentary portions of sexual organs now possessed by the higher animals, we are led to consider unisexual organisms to have been preceded by and to be descended from a type possessing both male and female sexual organs in a perfect condition, as is customary with many forms at the present day.

In the long process of evolution many species gained a decided advantage in the struggle for existence, in the disuse or loss of the organs of one sex, permitting the individuals of either sex to concentrate their energies in one direction; but, unlike Dr. Ambrook, I conclude that those which lost the ability for reproduction have suffered a degradation of type rather than an advance.

The superiority of the female, in a sexual or physiological point of view, seems to me evident, when we consider the necessity of reproduction to the continued existence of the species.

For instance, among plants which are sexually separate, that one is far higher in grade which reproduces its seed and fruit, than that which merely liberates its myriads of pollen grains to drift at the mercy of the breeze, though in their present stage of development each is necessary to the other. Among most insects, too, the life of the female is practically the life of the species, the male being little more than a perambulating spermatozoa holder, with just enough intelligence to enable it to seek its partner. That man and many male animals have reached a higher muscular and nervous development than the female is owing to their relinquishment of this highest and most vital function, reproduction, and consequently their liberty to direct their energies into other channels, the most important of which was probably the ability to struggle with rival males for the possession of the female. The individual advantages they have gained in freedom from the great vital drain and exhaustion of child-bearing have been more than compensated by loss of function. They have, as it were, *parted with their birthright* for personal independence. Although man, by his inheritance of superior mental and physical characteristics, is still able to produce a strong impression upon the embryo, it must be acknowledged that he is, in a sense, childless, and that in a natural arrangement of the family the children would derive their names as well as blood from the mother.

The law, as I would interpret it, is this: The ovum only is essential to reproduction. The spermatozoid is primarily non-essential—has no direct influence on the sex, nor is it always necessary to the life of the germ. This is a bold statement, which needs to be supported by strong arguments. I will instance several, though the list may be indefinitely extended.

Among many species of insects the females unite very irregularly with the males. The aphis can propagate a whole season, during sixteen generations, without the presence of the male. Their ova not only develop into adult insects without the aid of the spermatozoid, but, what is more uncommon, they become perfect females, filled with ova, which, in their turn, produce perfect females. On the approach of winter some cause—diminishing temperature or supply of food, diminishing vitality of the germ through the long chain of generations, perhaps all these combined, result in this: that the ova are not all capable of developing into females, but take the opposite sex; the necessary consequence of the failure of one set of organs or functions determining the flow of blood and nutrition to the other.

The remaining males and females then pair, and the next batch of eggs are laid, to hatch out the ensuing spring, and with renewed vitality to repeat the generative circuit.

In like manner the queen bee can lay ova which will develop without ever meeting the drone; but, unlike those of the aphis, all such progeny are male. It is only after uniting with the drone that she can produce female ova, and she can then produce males or females at will, by admitting or excluding the spermatozoid to the ovum.

Would Dr. Ambrook insist that the female alone can produce ova of a higher type (male) than she can with the assistance of the drone? The contrary statement is the only possible solution of the question. Or would any one argue that the spermatozoid supplied the sexual element? That is the way the boy reasoned when he defined salt as "a mineral that causes meat to stink by not putting any on." On the contrary, the conclusion is so plain that it is my only excuse for placing the subject before you, having never seen these views advocated and being unable to see how they have been overlooked.

The ovum of the queen bee was perfect; it subdivided, absorbed nutriment, and developed into the adult insect, only it lacked just that modicum of vitality to determine the flow of blood or nutrition to the ovaries, and to enable it to take its place in the female line and carry on the process of reproduction. Hence, of its two sexual possibilities, one, the most important, failed; and the second went on to development in its turn. The new insect can never reproduce itself, but through its spermatozoa is still capable of assisting another and more favored individual. Had the spermatozoid met that ripe ovum at the proper moment, its contents, rich in nitrogen, carbon, and that most stimulating of all cell-food, phosphorus, would have been absorbed into the ovum and supplied just that energy or vitality which before was lacking to produce the female. Further, as the bees need but one female in the nest, the interests of the family are best subserved by a modification of the remaining female ova into *workers*.

This is effected by supplying the young larvæ with a scant diet, which stunts the whole sexual apparatus, besides modifying the body and external organs of the bee in a wonderful manner.

In these cases the attempt to depress the vitality of the embryo was begun too late to affect the male organs, and can only prevent the full development of those of the female.

Mrs. Mary Treat, in studying the habits of several spe-

cies of butterflies at Palatka, Fla., a few years since, made some interesting discoveries in this connection. Of a large number of larvæ which she confined and fed profusely, almost all became females; while another batch selected at the same time and under the same conditions, but sparingly fed, almost all developed into males. Obviously the circumstances which in these experiments determined the sex were such as more or less interfered with the nutrition of the organism, and, acting while the sexual bias was undecided, turned the scale in a certain direction. Such investigations, conducted especially among insects, would throw a flood of light on the various causes which direct the flow of sexual energy; but it is probable that in most cases, particularly in higher organisms, the sexual bias is determined at the moment the ovum and spermatozoid unite, and long before the organism can be subjected to any influence outside the egg.

In applying my conclusions to animals of the higher types, it appears probable that their ova possess much less vitality; the size and complexity of the organism and its varied environment withdrawing much of the vital energies to other functions than the reproductive. Hence their ova invariably require the stimulus of the spermatozoid, without which they soon die, their sex in turn depending on the degree of vitality remaining in the ovum after its combination with the spermatozoid. I believe that in all cases those ova endowed with an excess of energy become female, and *vice versa*. At the very beginning of the separate existence of the ovum, when it is still but a single cell, the action of the spermatozoid upon it is probably that of a highly stimulant food increasing its capacity for future growth; yet, as this food undergoes no digestive change, but is bodily absorbed and mingles with the previous contents of the cell, it exercises an immense influence on the future being, second only to the original elements. Hence the progeny of a female resemble in some respects the male parent, though many, and in fact most, of its male characteristics may be inherited from its maternal grandfather. In defining a male we can hardly consider his masculine qualities as due to inheritance from his male parent; they are rather the sum of his inheritance from all his ancestry, back to the first separation of the sexes.

The female, then, is the type of the species—she is, I might almost say, the species itself; the male is only that form or modification of the species developed by the difference in his life and habits.

Holding the views I have here presented, the influence of natural selection in determining the relative proportions of the two sexes is easily understood.

When the vitality of the germ falls below a certain point, the resulting organism is a male whose sexual organs furnish the material necessary to raise the standard again above that point. In some insects, as the aphis mentioned, that influence lasts for generations; in others, as the bees, it affects only the sex of the particular ovum concerned, while in the higher animals the standard of vitality of the ovum has fallen to an extent which requires the presence of the male element in all cases, any further depreciation being resisted by the slight excess in the number of males.

Thus the internal forces constantly endeavor to correct the influences of the external.

In regard to methods of controlling sex, the possibility of devising anything practicable is very doubtful, especially in the human subject. The ovaries and their contents are developed at an early period of fœtal life, and the ova themselves appear to be very little affected by subsequent diseases of other portions of the body.

For this reason, women suffering with severe diseases, as consumption, may bear children of either sex unaffected, except as to want of nutrition while *in utero*. The testes are not so free from special disease, nor the spermatozoa so unaffected by the general health of the body, because an interference with the general health may interrupt their elaboration in countless millions in the testicle to a much greater extent than the ripening of a single ovum.

Nevertheless they do enjoy a remarkable immunity from disease in spite of that fact.

Any attempt at artificial selection will be likely to prove fruitless, since persons of superior muscular and mental development may be, for that reason, very poorly developed sexually.

A long list of exceptionally brilliant men might be given who have left no descendants, and not a few noted women, but the latter sex are not so productive in individuals of extraordinary qualities.

Women of strong mental and so-called masculine qualities are generally unfruitful.

Among animals, one fact has been noted which may have some influence on the sex. As they only mate at regular periods, the plan of influencing the ovum by an earlier or later fecundation has been attempted, and, as claimed, with some success, but the results are not yet on a sufficiently large scale to be reliable. A large breeder of dogs asserts that when the bitch has been served at the commencement of heat, she is more apt to produce females; if fecundation is delayed till near the end of heat, males. This is quite possible, and even probable, considering that an early impregnation of the ovum should insure its highest grade of vitality, and that, the favorable moment passed, its subsequent progress is toward disintegration and death.

Even this hint, valuable as it may prove to breeders of stock, is of no use to the human race, who unite more frequently, and in disregard of periods of ovulation; and even if this were not a fact, the meeting of the spermatozoa and ova in the Fallopian mazes is subject to so many uncertainties, and varied by such an immense personal equation, that experiment would probably be useless.

I cannot close this already too lengthy article without referring to a curious bearing of natural law upon human, or, may be, unnatural, laws. In man and many animals the embryo is known to exert in its turn a most extraordinary influence on the mother. Stock-raisers are aware that a domestic animal of pure breed, if once mated with a male of another breed, can never be depended on afterward to breed true. If this be a natural law, as is now generally admitted, the eldest child is more especially descended from the female parent than any subsequent offspring. Consequently the English law of primogeniture, while it aims to secure the inheritance steadily in the nearest male descendant, is necessarily an ingenious device for transferring the succession at each generation to an heir more especially descended, through the female, from another family. Where the mother happens to be an eldest daughter, her eldest child would be most nearly related to the *family of its maternal grandmother*. This is not a physiological enigma, but an inevitable corollary of natural laws.

ALBERT C. BEALE,
Hospital Steward, U.S.A.

ROCK ISLAND ARSENAL, ILL.

"CONTROLLING SEX IN GENERATION."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My attention was promptly called to your kindly notice of my book, with above title, in THE MEDICAL RECORD of December 26th last, by a medical friend of your city, and I ought sooner to have made some grateful acknowledgment to you for it. But expecting that your review would draw out some objections, or at least some inquiries from others, I deferred the thanks till I could see what these might require, and make one communication suffice for both purposes.

My home is in, or near, New York City, but I am spending the winter in this Southern resort, where I had not a ready access to the numbers of THE MEDICAL RECORD as they came out, which must be my excuse for this delay.

The difficulty which all new ideas have is to get a hearing. They are generally regarded as intruders and denied even a hearing. As Professor Tyndall says, "A great theory has never been accepted without opposition; . . . all have to push their way through conflict to victory." And when, after long years of experiment and research, a man succeeds in evolving a new truth that he knows will be of high value to his fellow-men, he is yet far off from the ultimate success which utilizes his work. Many a meritorious invention is strangled in its birth by the carping critics who "know it will not work."

When, therefore, as in your case with my book, a helping hand is held out by a stranger, and even in the face of his preconceived ideas the new idea is recognized as meritorious and worthy of being considered, it is an encouragement that calls for thanks in return, and please, sir, accept mine for this service.

It is over thirty years since the investigation of this abstruse subject first pressed itself upon my attention, and nearly twenty years since the first rough manuscript of my book was written. My book was, therefore, no hasty publication, and I have such confidence in the truth of the main theory, that I am emboldened to say you will never have occasion to regret the favorable notice you gave of the book.

In saying this I am not blind to the fact that much of the collateral matter, at least, is yet not proven to the extent that the world will accept it as positive. When, after long years of investigation, one becomes satisfied in his own mind that he has elaborated a true theory of the action of one of nature's many mysterious laws, if he would not let his life-work die with him, and all his labor be fruitless, he must put it forth, as it were, tentatively, with such confirmations and support as he has been able within his lifetime to gather. The theory then appeals to others interested in the subject, who may be investigating in the same or a different channel, for further confirmation or for refutation. Through the wide jurisdiction of such a tribunal some things in my book may have to be modified, but the general principle therein enunciated —that the stronger sexual energy of one parent at the moment of impregnation will control the sex of the offspring, throwing it to the other sex, will, I am sure, abide and stand. This principle embraces a wise and beneficent biological law, of universal application in the generation of all organic beings by sex, through which the equilibrium of the sexes in numbers is everywhere maintained. For, as soon as either sex, through unfavorable conditions, is so weakened that the offspring tends to one side, these offspring will have been so re-inforced from the strength of the stronger parent that they in their turn will produce offspring of the opposite sex, and thus the equilibrium will tend to be restored.

There is no such general law found in any other theory of sex advanced; in fact, the equilibrium is left entirely to chance.

Further, my theory will properly explain and embrace many, if not all the other, theories or conclusions of writers on the subject. For example:

Carl Dühring, in a series of articles in *The Jenaische Zeitschrift* (favorably reviewed by Professor W. K. Brooks, of Johns Hopkins University, in *The Popular Science Monthly* some months back), gives as a positive fact, from statistics, that "as the mares increased in number put to the same stallion, there were more male colts," showing that as the male's sexual vigor was weakened by more frequent service, the sexual influence of the female was oftener prepotent to the production of males. These statistics ran up to over one hundred thousand colts. Dühring further concludes from his statistics, that "a favorable environment causes an excess of female births, and is unfavorable to male births." His statistics show that he means by "favorable environment," city life, where is found more wealth and luxury—though I would deem this an unfavorable environment for the vitality of the human race. My book explains this on my theory, that the malign influences of city life bear more especially on women, reducing their sexual vigor to a greater extent than they do that of the other sex; hence their ability to conceive males is reduced.

The theory that sex is determined by the age of the ovum when fecundated, that in the early, or, as called, immature state, a female is generated, and later, in its maturity, a male, finds many advocates; and some have thought from their experiments it nearly, or quite, solved the mystery, though it would fail at times. At one period of my investigations I held a view somewhat kindred to this, but finding it incomplete, discarded it. And yet, if the reader will reflect, he will see it is but a phase of the principle I present. The conditions surrounding the production of the ovum tend to excite the sexual desire, which naturally has its first feeble impulse and increases gradually in intensity as the period of heat progresses, till the ovum is impregnated, or is lost. If impregnation occurs early in this period there is likely to be less desire and female offspring the result; if late along a greater desire with a better chance for male offspring. But it is obvious that a strong female in the first or weaker stage may overbalance a weak male; and a weak female, in the later or stronger stage, be overborne by a stronger male, so that contrary results will be produced.

It is unnecessary to multiply these comparisons, they are quite obvious to those who seek; and I therefore suggest to your readers who may be unwilling to accept this biological law of mine as positively true, that they try it as a working hypothesis for a time and see if they will not be satisfied and really astonished at the number of peculiar cases it will fit; as an example, that of the conception of a daughter mentioned in THE MEDICAL RECORD of February 13th, p. 186, second column.

And now in answer to the objectors. One, January 16th, p. 81, remarks:

(*a*) "It is probable that energy will result in a greater effect than listlessness . . . but how can it be proven that this energy is transmitted to the spermatozoa or ovule?"

Ans. By the results of sex different from the parent of stronger vitality, where all the children are of one sex.

(*b*) "None so capable as physicians to testify on this subject."

Ans. Very probable. Though they do not likely propagate more children than other men through which the parental conditions at conception can be most accurately known, they have better opportunities to observe these conditions in the wives of others, if they give it their attention.

(*c*) "Thinks sex is a degree or phase of development."

Ans. Quite possible, but not probable, that an incipient female develops into a male, or the reverse.

(*d*) "In bees the same egg, according to environment, develops into a neuter gender (the worker), or into a female (the queen), or into a male (the drone)."

Ans. All wrong. The so-called neuter or worker is a female, the analogue of a girl before puberty. The development of the procreative organs is permanently arrested by deprivation of proper food, which, in case of need for a queen, is supplied to the larva, not to the egg. Instances are known of the worker occasionally laying a few eggs. The male larva cannot be developed into a female, nor the female larva into a male.

(*e*) "Some lower orders (frogs) show signs of an ovary and a testes in same animal, and this a proof that the testes are a more highly developed, not a differentiated tissue."

Ans. Not a proof of a more highly, but of a different, development, as I treat of in my book. All men have paps, but this is no sort of proof that they could at any stage of existence have further developed into females.

(*f*) "Regards an excess of females in a family as indicating the physical degeneracy of the family." Instances the British peerage as showing this.

Ans. As the parents are from different families, have both families degenerated when the female offspring are in excess? I show that this condition indicates a weakened mother, or a father too ardent; and that it may run to the extent, on the mother's side, of a degeneration. If the degeneracy is on the father's side alone, boys will be born, but they will not have strong vitality, and likely die early.

(*g*) "It is a fact that a long time can pass before the wandering spermatozoa meets its shipmate" (the ovum), from which an inference that "sexual excitement at the time these were launched cannot determine the sex."

Ans. Even admitting a long time can pass (which I doubt, as conception occurring in mid-menstrual periods is no proof), the *vis vitæ* with which the male and female products were separately started would inhere in each at their meeting, and the same results would follow as if the junction was immediate.

(*h*) "The present summit of sexual development seems to be a male."

Ans. A woman would doubt that, as would the man himself, when satisfied that his three boys are due to their mother's vigor rather than to his. Thomas Meehan, of Germantown, State Botanist of Pennsylvania, a long-time observer in the field of sexual development in plant life, says: "In dicœcious plants the more vigorous shoots produce the females, the less vigorous the males," indicating that the female is the highest development, or at least the one which nature takes most care to perfect.

In reply to the objector in No. 795, January 30, 1886, p. 139 of THE RECORD, I remark, I have no experience with such abnormal cases as he presents, of women conceiving without any sexual desire. There is a general disposition in the sex to conceal this desire, because men, while vaunting their own sexual energy, condemn its exhibition in women. The most I have met in this way is the not infrequent excuse of unmarried women for having an illegitimate child, that conception occurred while they were asleep and unconscious. I never knew them to find many of their own sex, who had been wives and mothers, to believe them. However this may be, any repression of the exercise of this function in a healthy woman, whether through disinclination, prudery, or fear of pain from malformation, would add to the power when conception did occur, and thus operate to produce males, on the same principle suggested in my book, that a too frequent use of the sexual organism by women, through its weakening effect, tends to the conception of females.

In the communication "Women and Bees," February 13th, p. 195, there are only three points the writer makes against my theory, and these clearly show she never read the book. These are:

(*a*) "Doubts of there being any locality where more girls are born than boys."

Ans. Read the statistics in my book and be convinced. The New York records of births are very defective, and mostly record the foreign born, as I have shown. Instead of 30,030 births, there must have been, according to all ordinary rules of proportion from vital statistics, fully 50,000. There were 35,696 deaths; the increase of population per annum, aside from immigration, is two to three per cent., and the births should be at least 65,000 to make the annual increase of population *two* per cent. This rate would double the population in fifty years, while it is held to double by births over deaths in thirty-three years.

(*b*) A deduction that because I say "the more sickly the wife, the more debilitated the children," I "make female and debilitated synonymous terms."

Ans. My proposition is so self-evident that it cannot be doubted, but the correspondent's deduction is not a logical one. There is no foundation for it.

(*c*) That I "have not realized that it is not deficient passion, but deficient breathing-room, that cripples (kills?) boys. The nourishment fails . . . because her blood cannot enrich the milk that is made."

Ans. This is precisely what I have realized and teach. First, that a lack of vital power in the wife, found in certain environments, makes her often deficient in the sexual power, from which she is less able to conceive boys; and second, that, from the same lack of vital power in her, the boys she does conceive cannot be properly nourished after they are born, while the girls, with their ability to passively endure privation, survive on the inferior pabulum.

SAMUEL HOLCH TEERY.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 4, to April 10, 1886.

HARTSUFF, ALBERT, Major and Surgeon. Granted leave of absence for fifteen days. S. O. 71, Department of the East, April 7, 1886.

MCELDERRY, HENRY, Major and Surgeon, U.S.A. Ordered for duty as Post Surgeon, Fort Wayne, Mich. S. O. 69, Department of the East, April 2, 1886.

MERRILL, JAMES C., Captain and Assistant Surgeon. Granted leave of absence for three months. S. O. 81, A. G. O., April 7, 1886.

BIART, VICTOR, Captain and Assistant Surgeon. Sick leave of absence still further extended one year on account of sickness. S. O. 79, A. G. O., April 5, 1886.

BIRMINGHAM, H. P., Captain and Assistant Surgeon. (Camp Grant, New York City), temporarily assigned to duty at Fort Columbus, New York Harbor. S. O. 72, Department of the East, April 8, 1886.

LAUDERDALE, JOHN V., Captain and Assistant Surgeon. From the Department of Dakota to the Department of Texas. S. O. 79, A. G. O., April 5, 1886.

ADAIR, GEORGE W., Captain and Assistant Surgeon. From the Department of Dakota to the Department of the East. S. O. 79, A. G. O., April 5, 1886.

FINLEY, JAMES A., Captain and Assistant Surgeon. From the Department of Texas to the Department of Dakota. S. O. 79, A. G. O., April 5, 1886.

KILBOURNE, H. S., Captain and Assistant Surgeon. From the Department of Dakota to the Department of Columbia. S. O. 79, A. G. O., April 5, 1886.

GARDNER, E. F., Captain and Assistant Surgeon. From the Department of Columbia to the Department of the East. S. O. 79, A. G. O., April 5, 1886.

GRAY, WILLIAM W., Captain and Assistant Surgeon. From the Department of the East to the Department of Dakota. S. O. 79, A. G. O., April 5, 1886.

BANISTER, J. M., Captain and Assistant Surgeon. From the Department of the East (upon the expiration of his present leave of absence) to the Department of Columbia. S. O. 79, A. G. O., April 5, 1886.

CARTER, E. C., First Lieutenant and Assistant Surgeon. From the Department of Arizona to Columbus Barracks, Ohio. S. O. 79, A. G. O., April 5, 1886.

JOHNSON, R. W., First Lieutenant and Assistant Surgeon. From the Department of Dakota to the Department of the East. S. O. 79, A. G. O., April 5, 1886.

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. From the Department of Columbia to the Department of Dakota. S. O. 79, A. G. O., April 5, 1886.

ROBERTSON, R. L., Assistant Surgeon. On expiration of his present leave of absence will be relieved from duty in the Department of Texas and will report in person to Commanding General of the Department of Dakota for assignment to duty. S. O. 78, Department of Dakota, April 3, 1886.

Official List of Changes in the Medical Corps of the U. S. Navy during the week ending April 10, 1886.

DRAKE, N. H., Passed Assistant Surgeon. Detached from duty at Naval Hospital, Philadelphia, Pa., and ordered to duty at Naval Hospital, Brooklyn, N. Y.

FITTS, H. B., Passed Assistant Surgeon. Detached from duty at Naval Hospital, Brooklyn, N. Y., and ordered to duty at Naval Hospital, Philadelphia, Pa.

ANDERSON, FRANK, Passed Assistant Surgeon. Detached from Naval Laboratory, New York, and granted six months' leave from May 1, 1886, with the privilege of going abroad.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 10, 1886:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
April 10, 1886.....	5	8	40	2	16	60	4	0
Deaths.								
April 10, 1886.....	0	1	9	2	3	19	1	0

PARANOIA is the term adopted by German alienists, and gradually being introduced into this country, as a substitute for "*Primare Verrucktheit*" and "primary monomania."

WYOMING TERRITORY AS A PLACE FOR PRACTICE.—A physician living in Wyoming Territory writes, asking us about the West Coast of Mexico as a place for practice. He says: "We have one physician to every two hundred inhabitants in this place. Business of all kinds, for the present at least, is suspended, owing to the overproduction of lumber and coal, the staple products. I have been here two years, and am just barely making a small living for my family." We cannot give our correspondent definite information regarding Mexico. He had better write to the United States Consul.

"FACTS FOR THOUGHTFUL CHRISTIANS."—Under this title, the New York Medical Missionary Society says: "About forty millions of heathens die every year with scarcely any medical aid. There are two white missionaries to about one million of heathens. There is one medical missionary to about ten millions of heathens. Modern medicine and surgery appear miraculous to the heathens; it is often very difficult to prevent them from even worshipping a doctor. Their gifts in gratitude for medical aid would shame many Christians. A medical missionary can, to a large extent, obtain his own support. His medical skill will open doors otherwise closed to the gospel."

RESPECTS TO THE SPECIALISTS.—*The Quarterly Bulletin* of the Post-Graduate Medical School for April contains a poem, read at the annual dinner of the School, and entitled "The Specialists." The author begins:

> 'Mid sulphurous fumes, in antiseptics rich
> Enough to please our Peters—cure the itch,
> Great Satan [illegible] upon his throne,
> And when he found [illegible] he came
> Fiercely he muttered: "Twenty doctors more
> Within two days have come within my door,
> And now at last the news quite deafens me dumb—
> The porter says some Specialists have come.
> Should old ambitions once these fellows seize,
> If they put out their signs, take in their fees,
> Sure all my toils of little use would be,
> Then I must go, this is no place for me."
>
> The Demon rose, and shook from off his coat
> The yellow films of *U. S. Sulphur lot.*,
> Uttered a cough which all Hell's regions racked,
> And ordered out his baggage, to be packed.
> "I'll up to earth," he said, "for I must know
> Why doctors are now rattled on me so."
> Out into space he shot—a curious sight,
> The Devil bent on setting things aright.
>
> Now, since he knew the Old World quite too well
> To try to keep the doctors there from—She'll,
> He went to Boston, thinking that perhaps
> Since Holmes 'd resigned he there would find a lapse.
> (I pray my hearers to remove their frown—
> I mix the Devil with so good a town
> Because poetic doctors who must rhyme with pills
> Care do it best where there are seven hills;
> I'm sure, myself, that half the fame of Holmes
> From this unevenness of Boston comes.)
> And so from off her very highest mound
> Our new Asmodeus cast his eyes around:
> He saw the doctors' gigs below him creep,
> He thought the ruts they rode in rather deep;
> He saw great doctors whom big fees did fatten,
> He saw the lady-doctors whom they sat on.
>
> He saw a college, beautiful and old,
> He saw another where degrees were sold;
> He saw our Art lift up its banners high,
> But saw that quacks and mind-cures were close by.
> Yet 'midst it all he found such virtues grew—
> The righteous rigid, but the wicked few;
> The Devil thought, "I'll let this place alone,
> The case is one of gravel, not of stone."
> (The simile is old, but then I might
> In Boston be a little litho-trite.)
>
> As when a meteor skims earth's airy shell,
> Or doctor jumps at the obstetric bell,
> So Satan, leaving ancient Boston, down
> He in one breath flew to a Quaker town—
> (A town, dear friends, of which you've heard some talk;
> Its people say it's better than New York.)

The visit to Philadelphia is described, and the Traveller, not finding much there to worry him, starts for this city.

> "For sure," he said, "unless all stories lie
> The doctors there are all much worse than I."

On his way, however, he meets with an explosion, by which he sustained a convenient multiplicity of injuries.

> A much bruised party rose from up the ground,
> He'd every ill that's in the body found—
> A spine concussed, a fractured bone or two,
> A dozen sprains, his skin quite black and blue,
> Disordered function of each inner part,
> Uneasy stomach, damaged lungs and heart,
> But sweet philosophy some comforts bore,
> "I don't mind much," he said, "I've fallen before,
> And sure the fates do in my cause enlist
> To fit me for each New York specialist."

He visits the surgeons, the votaries of Neurology:

> "So great her Science, and so small her Art."

The Orthopædists:

> "Harmonious children of a thousand braces."

Also the Ophthalmologists:

> It is not strange—at least it is a fact—
> That Satan's *falls* had caused a *cataract*;
> Or that, with all the errors to him due,
> Some errors in refraction he had too.
> Some learned eye-men, therefore, soon were seen,
> Who ply the art that's based on cocaine,
> Atropia sulph., some glasses, and the trick
> Of snipping off the iris double-quick.
> But great among the specialists they rise—
> They made the Devil open both his eyes,
> And soothed them, so that when no longer sore
> Th' insatiate patient clamored still for Moore.

Finally the Gynecologists are gently dealt with, as follows:

> Besides, he found they'd stolen his own wares,
> And caught their victims all in painful snares.
> Some pleasures still in Satan's lot prevail,
> For he at least unquestionably is male.
> For him no gynecologist could seek
> Within persuasive specula to peek,
> Or, with some learned name his troubles labelled,
> Like Parliamentary motions, have him tabled.
> I'm sure that once the Devil stopped and prayed,
> 'Twas when he found that he could not be spayed.
> (O gentle Art, I'm sure I am not blind
> To all the good you've done for womankind;
> But once 'twas woman's part to cut and sew,
> While now to cut and sew her parts you go
> Too oft', perhaps. Might it not be a gain
> If you made less of womb and more of brain?)

PELVIC ABSCESS IN THE MALE.[1]

By T. HERRING BURCHARD, M.D.,

By reason of their comparative infrequence, the indefiniteness of their symptoms, and the natural difficulties in the way of diagnosis, pelvic abscesses in the male have not attracted the same surgical attention as have those occurring in the female.

The serious nature of the affection is quite as great, however, in the one as in the other, and its occurrence we believe to be more frequent than the meagre literature of the subject would lead us to suppose.

Indeed, in the standard English and American authorities, the subject is either entirely ignored or dismissed with a passing allusion—an omission that is especially felt when we are brought in personal contact with a case of this kind.

Five cases have fallen under my immediate observation. The last case I have the pleasure of presenting to the Academy this evening.

By pelvic abscess I wish to be understood as meaning a phlegmonous inflammation occurring in the superior portion of the pelvic cavity, below the cavity of the abdomen, from which it is separated by the pelvic reflections of the peritoneum, and above the muscular floor formed by the levator ani muscle.

It must not be confounded with abscesses of the abdomen—typhlitic, perityphlitic, etc.—nor with those originating below the levator ani, in the ischio-rectal fossa.

In the loose connective tissue which occupies this region, described by Richet as the *pelvi-rectal space* ("Traité pratique d'Anat. Méd. Chirurg.," p. 93, fourth ed., Paris, 1873), abscesses occasionally form.

From the peculiar anatomical construction of this space, with its bony lateral boundaries and its dense and almost impervious musculo-membranous floor, abscesses may originate here, producing most acute constitutional disturbance, and even very extensive local disorganization, and yet unaccompanied with any distinguishing symptoms that would call the surgeon's special attention to their existence. Not only this, but following the general law of abscesses to travel in the direction of least resistance, they will burrow internally to very distant parts without manifesting their presence by coming to the surface. Thus they will dissect their way through the foramina of the pelvis, and appear externally under the gluteal muscles; they have penetrated the acetabulum and destroyed the hip-joint (Mr. Morris, of Middlesex Hospital, London, amputated the thigh at the hip-joint in a lad of seventeen in such a case); they have dissected up the aponeurosis of the iliac muscles, produced necrosis of the ilium, and appeared (as in the case I shall exhibit this evening) upon the external surface of that bone. Or again (as in Case II. to be described), the abscess having emerged from the pelvic cavity, may travel anteriorly, following the course of the femoral vessels beneath Poupart's ligament, and make its appearance on the anterior surface of the thigh; or again, it may penetrate the hollow viscera and evacuate itself into the bladder, the rectum, or the peritoneal cavity. In fact, having once escaped its bony confines, there is no direction in which it might not travel.

Mr. Henry Morris (Ashhurst's "International Encyclopædia of Surgery," vol. v., p. 1024) divides such iliac abscesses of pelvic origin into two groups, (1) the sub-peritoneal, and (2) the sub-aponeurotic. The former, he claims, are prone to spread widely, in both an upward and a downward direction, reaching the upper boundaries of the abdomen, even burrowing behind the diaphragm; while the latter are more circumscribed, forming between the fascia iliaca and iliac muscle, and producing caries or necrosis of the bone.

Clinical history and symptoms.—The clinical history and symptoms vary naturally according to the acuteness or latency of the attack. Should the attack be acute, both the constitutional and local disturbance is proportionately the greater. In such cases the phlegmon forms rapidly, with great pain and corresponding febrile phenomena. Such an attack might readily be mistaken for one of general or circumscribed peritonitis. With the pain we have more or less abdominal distention, tympanitis, vomiting, flexion of the thighs, all of which are characteristic of that disease. Micturition is difficult or altogether impossible. The tumefaction may project into the rectum, setting up proctitis and tenesmus. Should the inflammation spread upward, localized or general peritonitis may result. "Inflammation beginning in the pelvic cellular tissue is anatomically prone to spread to the iliac fossa" (Morris, *op. cit.*).

Abscesses that form thus acutely are more likely to evacuate themselves spontaneously, in either the rectum or the bladder, than are those of a subacute or chronic character.

The following case, published by Dr. Bowditch ("First Medical and Surgical Report of Boston City Hospital," p. 64, 1870), is illustrative of the truth of this statement:

"A slater, aged twenty-five, was admitted into Massachusetts General Hospital, having fallen a height of thirty feet, striking his face and hands.

"Intense pain in the lumbar and umbilical regions, with bloody urine removed by the catheter, were the immediate symptoms. His condition grew worse. Pain was intense. Abdomen tympanitic and very tender. Later on an induration was detected deep in the left lumbar and hypochondriac regions. At the end of the fourth week, the abscess pointed in the left inguinal region. On introducing a tube into the rectum to relieve the flatulent distention of the bowels, an abscess was punctured, and a large quantity of pus with bloody mucus came away. The swelling in the inguinal regions and tympanites nearly disappeared thereupon; but pus continued to be discharged daily per rectum. The patient never recovered. The abscess refilled, and burrowed up into the inguinal region, and down under Poupart's ligament into the thigh. The patient died from phthisis consequent upon long-continued suppuration, within eleven months after the injury."

Just how speedily the inflammation may terminate in suppuration in these acute cases, it would be difficult to say. The inference is logical, that suppuration, when it occurs, occurs some considerable time before it makes itself manifest by external tumefaction. That the delay in getting the evidences of abscess is not due to absence of pus, but rather to the difficulty the pus experiences,

[1] Read before the New York Academy of Medicine, April [illegible]

on account of the depth of the suppurative process, in coming to the surface.

During all this time, however, the constitutional evidences of internal suppuration are more or less pronounced, and a carefully conducted examination at this stage may forestall and prevent many months of tedious suppuration with its attendant evils.

Chronicity, rather than acuteness, however, seems to be the rule with pelvic phlegmons in the male, except in cases having a traumatic origin. The affection most frequently occurs in the poorly nourished and cachectic, and in such inflammatory processes are slow and suppuration tardy. A widely diffused induration may pervade the pelvic cellular tissue months before its final breaking down into pus.

The diagnosis in such cases is often very baffling, owing partly to the inaccessibility of the parts affected, and partly to the perplexity of symptoms that arise from so many different tissues, organs, blood-vessels, and nerves being affected by the inflammation.

As bearing upon the clinical history, the following cases are submitted :

Case I.—C——, Scotchman, cloth-printer, forty years of age, was admitted to Bellevue Hospital, Ward 14, June 4, 1872, with the following history :

Always a hard-working, temperate man. Father and one brother died of phthisis. Mother died of cancer. General health prior to the attack fairly good. Eight months before, while sitting on a wet bridge fishing, fell asleep, and awoke after the lapse of an hour with a severe chill. Went immediately home and to bed. Had severe chills with high fever for seven or eight days. Excruciating pain in bowels, back, and thighs. Bowels became moderately bloated and constipated. Had darting pains through pelvis and in both testicles. Constant desire to pass water. Micturition impossible after first night. Passage of catheter caused great pain.

Had to be kept constantly under morphia or opium. Hot applications were made to loins and abdomen. About the tenth day an abscess discharged itself into rectum, perhaps a pint of pus escaping. Immediate relief experienced, which lasted three or four days. Discharge of pus from rectum then ceased. Pelvic pain returned, but not so severe as before. Fever also returned, with sweating. In less than a week the abscess burst again in the rectum, with immediate relief succeeding. Discharge of pus kept up all winter, the quantity sometimes amounting to a pint in twenty-four hours. Twice during the last two months discharge ceased for three or four days at a time. Pain in perineum, back, and abdomen immediately succeeded, accompanied with high fever.

On admission : Patient half moribund and very feeble, having lost over forty pounds in weight. Body jaundiced, and teeth and tongue covered with sordes. Abdomen moderately extended and tympanitic. Pressure over bladder produced deep gurgling in pelvic cavity. Rectal examination showed an irregular tumefaction high up in the pelvis. When counter-pressure was made over hypogastrium, excessive fetid pus escaped from rectum.

Diagnosis of pelvic abscess with septicæmia was made by Dr. McBride, House Surgeon.

Death occurred the following day.

The autopsy revealed an old abscess-cavity, the size of a small cocoanut, in upper part of pelvic cavity, reaching just above the brim, and containing perhaps a gill of offensive pus. Walls of cavity gangrenous and sloughy, but entirely shut off from peritoneal cavity by a dense layer of plastic material. No recent peritonitis. Pelvic veins filled with thrombi. An opening large enough to admit the little finger connected the abscess-cavity with the rectum. Pyæmic abscesses in liver and spleen.

Case II.—Seen in consultation with Dr. J. Grafton, Watertown, N. Y., August 19, 1873.

Mr. ——, aged thirty-two. Had been generally well up to a year ago, when he developed a severe gonorrhœa after a prolonged spree. This lasted off and on for four or five months, during which time he had a severe attack of gonorrhœal rheumatism of left hip-joint and knee.

His present trouble dated back some five months, and immediately succeeded the rheumatism. Patient was awakened from sleep by a dull pain deep in the perineum and a sensation of chilliness, although no distinct rigor occurred.

Pain became more intense, the abdomen began to bloat, and when seen by his physician the following day, there was well-marked peritonitis. This became general, and lasted nine or ten days. After its subsidence a small tumefaction was observed in the left iliac fossa. This ultimately disappeared. Some ten days later, while being lifted from bed to lounge, a sharp pain was experienced in the lumbar region, extending down into the pelvis. Pain increased greatly through the night, and the swelling reappeared in the left iliac fossa. Fluctuation being detected, a small abscess was opened without giving any relief. The following day, however, a deeper abscess burst through this opening and discharged nearly a pint of pus. The incision was now enlarged, and an oakum tent was carried down toward the floor of the pelvis. Great relief followed this, but despite every attention the abscess would fill, discharge itself through the fistulous opening, and refill.

During the summer a phlegmon formed deep in Scarpa's space. This was lanced. The finger introduced into the abscess-cavity followed the crural sheath beneath Poupart's ligament into the iliac fossa.

When I saw the patient, who had just come under Dr. Grafton's care, he was greatly emaciated and œdematous, and had well-marked waxy degeneration of the kidneys.

Two sinuses led by circuitous routes into the pelvic cavity, one through the inguinal region, and the other from the anterior crural. A large, soft catheter, introduced through the former opening, could be readily passed into the pelvis. Warm carbolized water, gently injected, caused a perceptible tumefaction on anterior wall of rectum, high up. Upon my suggestion, and with a view of establishing thorough drainage, a counter-opening was made at this point, and considerable necrosed tissue washed away. Drainage-tubes of oakum were introduced.

Improvement, both in the patient's general condition and locally, was very marked after this. An inter-current attack of nephritis caused death within the following fortnight.

Case III.—Seen in consultation with Dr. McKnight, of Brooklyn. A slight-built and delicate lad, aged seventeen, received a severe strain some six months before by being lifted by "the seat of his breeches" over a friend's head in play. Faintness, succeeded by vomiting and intense pains in back and down the thighs, followed. This pain in back and thighs continued about a month, and then, without apparent cause, the boy being in bed the while, it shifted from the back to the hypogastrium, and became distinctly throbbing in character. Paroxysmal pains shot down the sciatics and into the perineum. Defecation was invariably accompanied with great pain, and the bowels were permitted frequently to go a week without movement.

When I saw him, April 6th, in addition to the above the patient was badly cinchonized and almost absolutely deaf from quinine, which had been administered with a view of breaking up what was supposed to be a malarial or neuralgic condition. A most careful examination under nitrous oxide was now made, both externally, by rectum, and, as the boy was very thin, by conjoined manipulation, with bladder both empty and distended ; but neither tumefaction, induration, or any other cause, was found to account for his excessive pain, pyrexia, and loss of flesh. Within a few days after this, while straining at stool, an abscess burst within the rectum and discharged several ounces of pus. The most marked relief followed. Pus continued to be discharged for some days, and a permanent recovery followed. In recalling this case and

the thoroughness with which the examination was made, it was rather mortifying to learn that a dense mass of indurated cellular tissue posterior to the rectum, which at the time was taken for the promontory of the sacrum, in less than a week broke down in suppuration.

Case IV.—A cachectic and feeble old Italian was admitted to my service, Charity Hospital, June, 1883, with what was supposed to be a chronic suppurating bubo of left inguinal region.

A very unsatisfactory history of pelvic pain of two years' standing was obtained. He complained on admission of weakness, loss of flesh, and pain referred to the hypogastrium, perineum, and gluteal regions. There was partial incompetency of the sphincters.

On examination, an unhealed incision, leading into the rectum, above the internal sphincter, with a deep sinus running up into the pelvis, was found. The operation had been performed about a year previously—for what or by whom he did not know.

A vertebrated probe passed up this sinus to a depth of eight inches, and there met another probe passed through the abscess-cavity in the groin. Of this latter we could learn nothing definite except that it had been there for several months. With considerable difficulty a soft rubber catheter was passed through this opening and down into the pelvis. Injections made through this escaped by the perineal opening.

The patient refused to submit to any treatment and left the hospital. He presented himself at my office the following fall for charity. An examination revealed the upper opening closed, the perineal sinus still open. A vertebrated probe readily passed about seven inches.

Case V.—Peter M——, aged twenty-eight, married, a porter by occupation. Always temperate, robust, and strong up to March, 1882, at which time he was suddenly seized, after some unusual exertion, with sharp pains in the right iliac fossa, which lasted thirty hours. This paroxysm terminated in a dull, heavy pain, which extended across the hypogastrium into the left iliac region, and has continued with greater or less severity up to the time of the operation.

In June 1884, he was admitted to St. Luke's Hospital, suffering from the same intense pain. Poultices were applied, but no suppuration occurred. The diagnosis of typhoid fever was there made.

In the following August, after several unsuccessful aspirations, an abscess of the right lumbar region, midway between the iliac crest and ribs, was evacuated by the late Professor James L. Little. The case was regarded by him as one of perityphlitic abscess.

At this time patient's condition was very bad. Severe pain deep in the pelvis and perineum. Darting pains through the rectum into the right testicle and down the sciatics. Priapism, with involuntary nocturnal emissions.

In December, a second abscess formed and was opened by Dr. Little. Although suffering more or less constant pain his health improved during the winter; but in March and July following, other abscesses formed in the side and over the body of the ilium. These were also opened. In August and September he had the pain and constitutional disturbance of forming abscesses, but free incisions failed in giving vent to pus.

October 5th.—Patient's health evidently failing. All the old pains have returned. A careful examination under ether was made by me, Drs. Seneca D. Powell and Henry A. Mandeville assisting.

Owing to the thickness of the abdominal walls from fat, this was very unsatisfactory. Rectal examination revealed nothing.

A localized phlegmon over the ilium, two inches below and to the front of the posterior superior spinous process, was opened and carious bone detected. This was removed by gouge and rongeur. The superficial caries led into a large abscess-cavity in the ilium, and this in turn communicated by a direct opening with the iliac fossa. The finger introduced through the bone could detect nothing abnormal within the abdomen. The carious bone being thoroughly removed, a tent of bichloridized oakum was introduced through the ilium, and the wound partially closed.

October 29th.—After great pain, referred to the hypogastrium, right iliac region, and right testicle, another abscess formed and discharged through the opening in the bone. The source of this could not be detected, and both external and rectal examinations failed to throw light on the case.

In early December another abscess formed within the pelvis, and, instead of discharging through the opening in the ilium, pointed over the crest and was evacuated at this point.

The patient's condition was now critical in the extreme. He was rapidly losing strength and flesh, and was being worn out with constant pain and suppuration. Albumen with hyaline casts appeared in his urine. It was felt that something effective ought to be done, and yet there was nothing tangible upon which to found a diagnosis beyond the fact that, at irregular intervals, abscesses in the right iliac region would form and discharge. Repeated examinations were negative in their results.

From the first the case was regarded by my assistant, Dr. H. A. Mandeville, as one of abdominal abscess of deep origin, and the carious bone as secondary to that; and hence from the first he advocated an exploratory abdominal section.

From this I at first differed, thinking the recurrent abscesses were due to the bone disease. In either case the indications clearly were to open the abdominal cavity (of course employing every antiseptic precaution), and, if possible, by stripping up the peritoneum from the right iliac fossa, to seek and remove the source of irritation.

In this opinion we were supported by Prof. R. F. Weir and Dr. H. Marion Sims, who kindly saw the case with me.

Operation.—St. Elizabeth's Hospital, February 13th, Drs. Sims, Mandeville, and C. W. Stimson assisting. An incision was made, commencing just above and posterior to the posterior-superior spinous process, and following the bone downward for a distance of five inches. The dissection was carried through the abdominal muscles and the peritoneum exposed. This I endeavored to detach from the subjacent fascia, but so firmly adherent was it that, in spite of very gentle manipulation, it tore. A flat sponge was introduced through the laceration to hold back the intestines, while with the hand a thorough exploration was made. Almost immediately a mass of adhesions were found that led to an old abscess cavity, which occupied the posterior half of the fossa, and that extended like a great sinus directly from the ilium, over the line of the pelvis and down into its cavity.

No dead bone could be detected. The sinus having been laid open, its walls, which were almost cartilaginous, were thoroughly revivified with a dull curette. The sinus through the bone was likewise curetted and some carious bone removed. Two drainage-tubes of soft rubber, eight inches long, were carried directly to the bottom of the sinus, and the whole thoroughly irrigated with a solution of bichloride of mercury, 1 to 2,000. The abdominal wound was now closed with deep and superficial sutures. The incision leading through the bone was kept open and dressed from the bottom with iodoform and bichloridized oakum. A superficial dressing of borated cotton was made over all.

The patient rallied nicely. On the third day the temperature rose to 102⅕°, and the pulse to 120, and there was a very slight circumscribed peritonitis. On the sixth day the patient's temperature was practically normal, and the discharge from the tubes scarcely amounted to half a drachm. After this the tubes were shortened gradually, and at the end of three weeks were entirely removed, firm granulations having filled up the cavity of the sinus.

The opening through the bone has likewise been filled

in with new tissue, and is now closed. To-night I have the pleasure of exhibiting the patient in better health than he has enjoyed for years.

Diagnosis and treatment.—The length of this article precludes any elaborate presentation of these important subjects, the object of the paper rather being to call attention to a much neglected class of cases.

It must be remembered, however, that whenever cellular tissue exists in the body, there suppurative inflammation is likely to occur. The male pelvic cavity, as the grossest dissection will show, contains a large amount of cellular tissue, and pathologically it is no exception to the rule.

Inflammation occurring here manifests itself in addition to local distress or pain, which is generally severe in character, by the usual constitutional disturbances. After tumefaction has occurred, another set of symptoms arise, which are due to pressure on sensitive nerves and organs. Recall in the histories cited how uniform have been the pain in the hypogastrium and pelvis, the excruciating pains down the sciatics and into the testes and rectum. Another feature peculiar to these abscesses is their tendency to burrow, and the very great dangers attendant thereupon. Their natural destination should be the perineum, and such doubtless would be the case, were it not that the extremely dense fibres of the levator ani and prostatic muscles, which are largely composed of firm fibrous tissue, present an almost impenetrable obstacle.

The next most natural route would seem to be the rectum, and here many of these abscesses are evacuated. Many, however, mount the pelvic cavity and appear within the abdomen, as the pelvic abscesses.

After this, their course is erratic. Most of the abscesses appearing anterior to the bladder, in the so-called *Cavum Retzii* (after the distinguished Swedish anatomist, Retzius), the prævesicular abscesses of French surgeons, are abscesses of pelvic origin (see a most interesting account of such by Leusser in Langenbeck's *Arch. für klin. Chirurgie*, No. 32, vol. 4, p. 851).

Clinically, it is important to distinguish between an inflammatory condition pure and simple—a cellulitis simplex—and the same condition after it has passed into a suppurative stage.

The presence of pus cannot be recognized at too early a period.

It is likewise necessary to distinguish between a pelvic cellulitis and general or localized peritonitis; also between this and cystitis, proctitis, and prostatitis. Rheumatism and neuralgia must be borne in mind.

Surgically, it is necessary to differentiate between abdominal abscesses, ileo-pelvic abscesses, pelvic abscesses, abscesses of the ischio-rectal fossa, and perineal abscesses.

Exceptional possibilities must be carefully considered. Hernia strangulated in the pelvic foramina; passage or impaction of renal calculi; acute inflammation of the psoas muscle; typhlitis and perityphlitis; and lastly scrofulous, malignant, tubercular, and syphilitic disease of the pelvic glands.

Treatment.—The treatment naturally resolves itself into treatment of the cellulitis before suppuration, and treatment after suppuration is established.

In the former case, rest, morphia, quinine in free doses, local refrigeration, and possibly local depletion by leeches to perineum. In employing cold in this or any other inflammatory condition about the rectum, nothing equals in efficacy and comfort, in my experience, the continuous use of cold water, which passes up and immediately returns through a double-flow blind tube. The great mistake that is often made by the inexperienced in the application of either this or the ice coil is in applying it too cold at first. The water at first should be warm, then gradually cooled until ice-water can be used, with astonishing relief. During acute inflammation frequent rectal explorations should be desisted from, as calculated to do more harm than good. After suppuration may reasonably be suspected a careful examination under anæsthesia should be made, in order that the abscess may be evacuated into the rectum at the earliest possible moment. If evidences of internal suppuration persist, and there is reason to believe the pus to be burrowing upward, an abdominal exploratory incision is obviously demanded.

If this can be made without opening the cavity of the peritoneum, it certainly should be done. The object to be attained, however, is the evacuation of the pus. We cannot always be successful in this. Adhesions will form impossible barriers at times. Mr. Tait met with failure in such a case in a male. The principle, though, is surgical and conservative.

MEMOIR OF AUSTIN FLINT, M.D., LL.D.[1]

By A. JACOBI, M.D.,

PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE.

The life of Dr. Austin Flint, one of my most distinguished predecessors in the presidency of the New York Academy of Medicine, was singularly fortunate. We may say that now that he has passed away, and avoided the dangers incident upon any human existence, which made the Greek philosopher exclaim that nobody must be called fortunate before he died. His birth, his life, and finally his sudden and painless death are peculiarly happy.

In the year 1638 Thomas Flint emigrated from Derbyshire, England, to Concord, Mass. Thus the family, of Puritan stock, is one of the oldest of the country. Austin Flint's father, grandfather, and great-grandfather were physicians in Massachusetts. Thus both the number of ancestors, and their labors and culture, constitute what even in this our country we may claim as genuine aristocracy.

This term I do not wish to be taken in anything like its usual European meaning. The aristocracy of the continent of Europe, hundreds of years ago, was composed of the men who spent their days in idleness, robbery, and violence. Their right consisted in the strength of their swords and the elasticity of their consciences. It required the invention of powder and guns to make their castles useless, change the hitherto unprotected into dangerous adversaries, and thus render the aristocrat virtuous. This compulsory virtue changed them into willing servants of the princes, whom they obeyed, either on the battlefields or in the waiting-rooms. They and their offspring, unless they have consented to take part in the physical or intellectual labors of the world, have contributed nothing to the development of morals and culture.

This is not what we may designate aristocracy in America. Our country has the advantage of not suffering from the evil inheritance of the mediæval period. What it has grown into being, it has become by hard work both of hands and brains. That kind of aristocratic family was the one Austin Flint hailed from; in it he might well have rejoiced, though pride would never be pardonable in anything accidental and not accomplished by one's own efforts.

With such hereditary advantages he was born in Petersham, Mass., on October 20, 1812. They were followed by those resulting from a liberal education in Amherst, and in Harvard, where he graduated in medicine in 1833. Since that time, without any interruption, he has been in the practice of his profession, adding to the daily practical labors much and varied literary work, and for the last forty years constant services as a teacher of medicine in six different colleges.

In Northampton and Boston he practised three years, until he moved to Buffalo, N. Y., in 1836. Here he resided sixteen years, with the intermission of a short period in 1844, in which he taught clinical medicine in Rush Medical College, Chicago. He founded the *Buffalo Medical Journal* in 1846, and edited it through a course of ten years; he organized, in connection with Frank H. Hamilton and James P. White, the Buffalo Medical Col-

[1] Read [illegible] the New York Academy of Medicine, at the Stated Meeting, April [illegible].

lege, in 1847, but left Buffalo in 1852 to take charge of the chair of clinical medicine in the University of Louisville. Thence he returned to Buffalo in 1856, spent the winters of from 1858 to 1861 in New Orleans, teaching medicine and attending Charity Hospital, and settled in New York in 1859. His position as the teacher of clinical medicine in the Long Island Medical College he resigned in 1868; the same chair in the Bellevue Hospital Medical College he retained to his end. Its last Commencement took place while he lay dead in his house, and a day before he was carried to his last silent home.

As a teacher he was eminently successful. Thousands of the present practitioners of the United States were his pupils; there is no county but has those who listened to his lectures; and there is none but who gratefully remembers the breadth of his knowledge, and the systematic clearness and elegant simplicity of his diction.

Whoever has not listened to him in the lecture room has made his acquaintance by his writings. For forty years he has contributed largely and worthily to the medical literature of the country. Many of his first papers appeared in the *Buffalo Medical Journal*, which owed the high regard in which it was held mainly to his contributions. From 1848 to 1850 he published articles on diabetes, the pathology of typhoid fever, on the epidemic of cholera in Buffalo, on serous effusions into the arachnoid cavity, on pleuro-pneumonitis complicated with pericarditis, and on fifty-two cases of typhoid fever. These essays were followed, in 1852, by clinical reports on continued fever and on variations of pitch in percussion and respiratory sounds, and their application to physical diagnosis; in 1853, by clinical reports on dysentery, and on chronic pleurisy; by (1856) his physical exploration of the chest and the diagnosis of diseases affecting the respiratory organs, and (1859) his practical treatise on the diagnosis, pathology, and treatment of diseases of the heart. In 1865 he wrote his compendium of percussion and auscultation, and of the physical diagnosis of diseases affecting the lungs and heart; and finally, in 1866, his treatise on the principles and practice of medicine.

It is not necessary to enumerate his many essays and papers, before and after that time. The publications of the United States Sanitary Commission, and the better journals of the country, bear evidence of his ever increasing experience, willingness to contribute to the common stock of knowledge, and the eagerness of the journals to print his papers.

His literary reputation was deservedly a very great one. Some of his works have been translated; his treatise had an immense sale. The method and mode of his writing is characteristic and instructive; if some of the modern writers would imitate him, it would be better for them and for literature. It is apparent that for many years he wrote nothing but clinical reports and studies. They were papers replete with careful observations plainly described, with their immediate results. These were followed, when his experience grew and his judgment became matured, by monographs on special subjects. He was fifty years old, and already a celebrity, when he published a treatise on the whole subject of internal medicine. It was the work of a man who had given two dozen years and more to the study of his subjects before venturing before the profession with his great book. Let the young manufacturers of text-books of nowadays, who collate the pigeonholed pilferings from the older books of better men into a volume, and try to build up a reputation with its hoped-for pecuniary advantages, learn from Austin Flint the period of life in which a man may be expected to write a text-book for the use of either the student or the physician.

In his writings nobody ever was more straightforward and honest. What he did not know he would not state. When he felt that the latest editions of his text-book could be made more scientific and serviceable by elaborating the pathological anatomy of his themes, he selected William H. Welch to write the required chapters, and gave him full credit for his work in his preface. As he was modest in his writings, so he was in discussions. He was always as anxious to be taught as capable to instruct. Some may remember a discussion on pepsin in the American Medical Association, many years ago. When, the next day, he received a note from one of those present, in which the necessity was urged to add muriatic acid to the doses of pepsin he had advised, he called in person to express his appreciation of the, then new, suggestion and the letter containing it. There was, however, one thing he was jealous of, viz., the honor of his country. When, in a discussion, he once complained of the oblivion of Carr's name in connection with the causation of the crepitant râle, and the pre-eminence attributed to foreign authors in regard to the explanation of respiratory sounds, he was rejoiced and proud when he was shown the page on which Winterich gives full credit to the American practitioner. Vanity and exalted opinion of himself were not his faults. He would never have accepted the eulogistic exaggeration proclaimed in a recent obituary, in which it is claimed that nobody in this century has done so much as he, or more than he, for the diseases of the respiratory organs. He would have urged that friendship and esteem must never go so far as to obscure the names of Laennec, the Frenchman, Skoda, the Austrian, and Stokes, the Briton.

Still, he was original in many things. His discussions on pitch and resonance will always be read with pleasure and profit. Though we owe him no great discoveries, we and our successors shall always admire his clear way of dealing with known facts and new observations, and of popularizing for the medical mind the latest evolutions of medical thought and the most mature fruit of scientific research.

The peculiar qualities displayed by Austin Flint the writer he would also exhibit as a teacher, both didactic and clinical. He taught general medicine, and preferred to study, and give particular attention to, the diseases of the systems of respiration and circulation. He was clear, painstaking, and accurate. He occupied a chair in which there are, to the average student, no amazing features or feats. The student who applauds when a bone is sawed through, or a spouting artery is caught by a dexterous hand, or the actual cautery sends fumes and odor through the amphitheatre, is quite apt to gaze with sleepy indifference at the master whose lips utter the finest points of a difficult diagnosis, or whose brain is exercised over the greatest intricacies of pathological physiology. In the teachings and the daily work of the practitioner there is rarely anything surprising, amazing, or brilliant. In spite of that, it did not take long for Austin Flint to make a great and ever-increasing reputation as a teacher. Let our young men never forget, and let them learn from the example of the illustrious dead teacher, that a good preliminary education, systematic work, earnestness, and solidity are the corner-stones on which alone a teacher and an author can build up a name worthy to be enjoyed and capable of being handed down to posterity. What Flint's importance as a teacher has been, and will be, can be best proven by his thousands of pupils. Still, even as fortunate and successful a man as he was has his disappointments and curtailments. One ambition of his life was never fulfilled.

Look at this fact: At the meeting of the American Medical Convention, since called Association, at New York, on May 5, 1846, he was appointed on a committee to report on a resolution offered by Dr. Isaac Hays, for a uniform and elevated standard of requirements for the degree of M.D. in all the medical schools of the United States. The report is signed by R. W. Haxall, Chairman, and can be found on pp. 63–77 of the "Proceedings of the National Medical Conventions, held in New York, May, 1846, and in Philadelphia, 1847" (Phil., 1847). The very first of the ten resolutions embodied in that report is this: "That it be recommended to all the colleges to extend the period employed in lec-

turing from four to six months." And it is true what a late number of a journal[1] says: "That that report is still to-day a most interesting, applicable, and valuable document." But alas! the slowness of spontaneous evolution, and the predominance of circumstances, and the weight of impediments are such as to cripple even a strong man like Austin Flint, who, though his life was spared long, never saw the hopes of his younger years fulfilled.

His successes as an author and a teacher were equalled by those accomplished in his consulting practice. In those special branches to which he had given so much of his time and attention, his counsel was frequently requested. No matter whether he had anything new to say, or had only to confirm the diagnosis or fortify the position of the practitioner, everybody here knows that he was always kind, mild, and modest. There is nobody here but has often either admired his superior knowledge and experience, or blessed his pleasing demeanor and generous words. He was an eminently just man and, for that reason, could afford to be mild and generous.

These qualities he exhibited in a period which has been a critical one in the development of the last few years in the life of the medical profession. During the first successful year of preparations for the International Congress he was true to the *bona fides* entered upon in Copenhagen. From the very beginning he was, like all the greatest and wisest men in the profession of both this country and Europe, earnest in excluding medico-political differences and difficulties from the organization of the Congress. In regard to the latter there was to him no Code question at all. I have good reason to believe that the demoralization and disorder in the ranks of the profession, growing out of these differences, caused him the greatest possible pain, and many of the most unhappy days of his life. It is a great satisfaction, however, to know that everybody wished to distinguish and honor the man who had served the profession half a century, to his credit and to the advantage of his fellows.

In regard to important moral and ethical questions, it is of graver import to study a man's own words than to listen to what others would wish us to believe; and when that man is Austin Flint, that mode of inquiry is still more indicated. Not that the Code question is so grave as some would have it. Indeed, it has begun already to have a historical interest only.

But some time ago everybody took sides in regard to the Code question. So did you, so did I, so did Austin Flint. But to belong to a party does not mean to be an offensive partisan. And if ever a party man—so I believe—was impartial, that man was, or tried to be, Austin Flint, whom we honor as much for his words as his actions. When a man works himself up into celebrity, his memory must serve the surviving as did his life. His opinions ought to be learned from his own papers published in the *New York Journal*.[2] Read them as if he were still among you. He is among you. For those who have lived a life worth living do not die. I am willing to abide by the platform laid out in those essays. They contain the same thoughts expressed by your presiding officer in an address delivered from this place on October 1, 1885. Two days afterward that address appeared in print. Two days after its publication I received from the great and good man who is now gone a letter which I shall be proud of preserving as a legacy. I hold in my hand this note of Austin Flint's, which begins with the words: "I have read your address with pleasure"—and finishes with these: "How beautiful, lovely, and salutary it is to promote peace, harmony, and brotherhood."

On the evening of his inauguration as President of the Academy, in 1871, his predecessor, one of the most illustrious types of American erudition and versatility, Edmund Peaslee, had a right to say to him: "We have always found you the high-minded and sympathetic man, and the genial gentleman, as well as the finished scholar, the distinguished author, and the skilful practitioner."

All that he proved during his presidential term which extended over the two years, from 1871 to 1873. The routine work performed during that time did not differ much from that of many other years or terms, but some of the papers were of unusual excellence. It would be improper to go into the merits of the essays read and discussed. They were by Allen S. Church, Charles A. Leale, Willian Detmold, Alfred A. Loomis, Samuel S. Purple, Charles P. Russell, Gouverneur M. Smith, J. Lewis Smith, Frank P. Foster, Gurdon Buck, Ernst Krackowizer, J. C. Dalton, Lewis A. Sayre, E. C. Seguin, Salvatore Caro, and Allan McLane Hamilton.

Flint's contributions to the scientific work of the Academy were not numerous, but their character was high. Amongst others, "The Management of Pulmonary Tuberculosis, with Special Reference to the Employment of Alcoholic Stimulants," June 3, 1863 ("Trans.," ii., p. 353); "Discussion of Dr. Leaming's Paper on Pleuritis," March 17, 1870 ("Bulletin," iv., p. 48); "Discussion on the Etiology and Pathology of Bright's Disease," October 1, 1862 ("Bulletin," vol. ii., p. 1); "Discussion on Dr. Loomis' Paper on Typhus Fever," February 15, 1865 ("Bulletin," ii., p. 388); "Last Illness of Valentine Mott, M.D.," May 3, 1865 ("Bulletin," ii., p. 434), will always be referred to with sincere pleasure.

His membership in the Academy ceased a few weeks before March 13th, on which he breathed his last. You remember the universal reluctance on the part of those present to accept his resignation, and the silence with which the remarks of the presiding officer were listened to. *Malevolence only could misconstrue, and has misconstrued, into their opposite, his words of appreciation and regret.* There is one great gratification even in that resignation of his. His good will toward the Academy is best exhibited by his staying as long as he did, under rather peculiar circumstances, and moreover we shall know, by the gift or his library which he bequeathed to the Academy, that the latter was dear to his heart. For the Academy not to speak words of praise and remembrance in behalf of his memory, in this hall which he graced and in which he taught, in spite of suggestions and even demands to the contrary, of a personal character; not to keep his memory green among us, is an impossibility. As it is for us, so for the medical men of the country. His name and reputation form part of the history of our profession, and this Academy means to honor its dead who have gone into history.

In listening to or reading the eulogies of the dead, I have often been struck with the well-meant, but still obtrusive, exaggerations of their characters and services. It then appeared to me that the writer buried the memory of the friend under an oppressive weight of high-strung flatteries. It reminded me of the manner in which an inconvenient beggar is forever cast aside by buying him off with a large sum. That plan may do well enough for the mediocre, who never excelled, and therefore is extolled for once. But if there be any among us who rise above mediocrity and average, or those even whose intellectual stature fills a large space between the soil on which their feet walk, and the skies to which their brows are turned, let them, while they live, harbor the ambition, or when they are dead, enjoy the honor of serving mankind even after and through their very deaths. To accomplish that, let the truth be stated, and the truth only. Thus it was the truth only I aimed at in this brief sketch. As its object was great, I found it an easy task to omit the trite platitudes of a commonplace eulogy.

Austin Flint had great advantages, and developed and utilized them for the benefit of the many. Born with an enviable inheritance, he enjoyed a thorough general and special education. He had great physical endurance and uniform health, an imposing presence, pleasant manners, and an equable temperament. With physical

[1] Journal of the Am. Med. Assn., Minneapolis.
[2] Appleton's Journal for Literature, Science, etc.

and intellectual powers he combined indefatigable love of work, which he performed systematically and energetically. He was a thoroughly modest man, who knew how difficult it is to master the depths of knowledge; thus he had an unusual degree of common sense, which limits aspirations and aims. Thus he became thorough in what he undertook to practise and to teach. Thus he was successful in practice and enjoyed the confidence of both the profession and public. As a teacher he is remembered by thousands; his pupils loved him and his colleagues honored him. His writings obtained for him a national and international reputation. There was no place of honor in the possession of the profession of the city, State, or country, which he has not filled. The profession of Europe was anxious to show its respect for him. Thus he lived and worked to an advanced age, disturbed by but few symptoms of evanescing powers, and when the time came he ceased to labor and live on the very same day.

As a profession, let us hope that we shall have many like him.

REMINISCENCES OF PROFESSOR AUSTIN FLINT, M.D., LL.D.[1]

By J. LEWIS SMITH, M.D.,

NEW YORK.

In 1836, Professor Flint, in his twenty-fifth year, and three years a graduate in medicine, commenced the practice of his profession in Buffalo, without acquaintances and with no reputation. In a young and bustling city, with few facilities for study and improvement in medicine, he possessed the qualities which enabled him to create the opportunities which he needed, and to make in time the city of his residence one of the medical centres. Buffalo, at that time without a medical organization worthy of the name, with physicians intent on acquiring and retaining a practice, having no regard for the higher demands of the profession, did indeed seem an uncongenial and unsuitable place for Professor Flint, whose highest ambition was to improve in medical knowledge, and whose life-long endeavor was to make discoveries in the nature and treatment of diseases which would benefit the profession and the world.

Among the first diseases investigated by Professor Flint after his settlement in Buffalo were those due to marsh miasm, and it was not long before he had made a sufficient number of observations to enable him to publish some novel but correct views in reference to their treatment. In 1841, forty-five years ago, the *American Journal of the Medical Sciences* published from his pen a statistical paper, designed to show that intermittent fever, which he had treated among the troops stationed at Buffalo, required no preparatory treatment by mercurials or otherwise before the use of quinine, and that quinine would control the disease more certainly and with safety, if given in the intervals of the paroxysms in as large doses as ten or fifteen grains. Both these opinions, then new to the profession, and contrary to the usual practice, attracted attention, since they were supported by statistics; and, as we all know, they are now accepted as true, and the present mode of treating the disease is the same as he recommended.

In the same year he published a paper on dyspepsia as related to the state of the mind. From this time, during his entire life, he was a frequent contributor to the medical journals. Among his early papers, that to which I think he attached the most importance bore the title, "The Pathological Relations of the Medulla Spinalis;" it was published in the April number of the *American Journal of the Medical Sciences*, in 1844. This paper was also statistical, the views expressed in it being derived from an analysis of fifty-eight cases. The opinions contained in this article, as well as the instruction upon the same subject, which in former years he never failed to give to each class of students, have been of great value to the profession. Patients in a depressed state of system, and especially the anæmic, frequently have pain and tenderness at some point upon the lateral or anterior aspect of the trunk, and pressure along that part of the spine where the nerves originate which supply the affected part increases the pain, and is therefore a safe and certain means of diagnosis. When pressure upon the spine intensifies the pain, the latter is neuralgic, and not inflammatory; and yet the mistake is often made of diagnosticating an inflammation, and treating the patient accordingly, when the simple test mentioned above would have corrected the diagnosis.

Professor Flint recently stated to the writer that many years after the appearance of his paper in the *American Journal of the Medical Sciences*, he was still more deeply impressed with the importance of the subject upon which he wrote, when in accompanying the most distinguished clinical teacher in Europe through the wards of a Parisian hospital, he was able to correct, by the simple tests with which he was familiar, the diagnostic error of the professor, who had stated that one of the patients whom they were examining had "*péritonite*."

My acquaintance with Professor Flint commenced in 1851, when a medical student in the Buffalo Medical School. The *Buffalo Medical Journal*, established and conducted by him, was then in its fifth year. From the ability apparent in its editorials and original articles, many of them from his pen, it was widely taken in Central and Western New York, in the adjoining States, and in Canada, and it no doubt aided very much in drawing students to the Buffalo Medical College, then in its fourth year, and in which he held the Professorship of Theory and Practice.

At this time he read his lectures, and they were listened to with interest and always by the entire class. It was not, however, till the following year (1852), when, as an advanced student, I was appointed one of the house staff of the Hospital of the Sisters of Charity, that I became more fully acquainted with the subject of this sketch. No one more highly appreciated hospital advantages as affording the opportunity for medical improvement than he at this time, and indeed through his whole life. He had previously made use to the best advantage of the clinical opportunities which the old almshouse afforded, and now he had the privilege of studying diseases among a better class of patients, and with better surroundings. During my stay in the hospital every case in the service of Professor Flint that possessed any interest was recorded in his note book, and his thorough examination of patients, in order that the notes might be complete, necessitated a prolonged stay on his part at each visit in the hospital.

The late Professor Bennett, of Edinburgh, said that "a large metropolitan practice is the bane of the profession," since it prevents the proper examination of cases, and the investigation of subjects which are of interest to the profession. Professor Flint appeared to have the same belief, for he seemed annoyed and disappointed when professional engagements in the city prevented his daily visit to the hospital, or compelled a shortening of his stay there. It was apparently his endeavor that each day should add something to his stock of medical knowledge, and to a better understanding of the diseases which he met in the hospital.

It may not be improper to state that at this time some of the more prominent physicians of Buffalo, who had not participated in the founding of the college, were not in sympathy with it. This hostile element in the profession was represented by its ablest men in the board of visiting physicians of the hospital. The college, of course, sustained little injury, for it had a strong faculty, consisting of such men as John C. Dalton, Frank H. Hamilton, George Hadley, and James P. White, but the consciousness of living and working in an unfriendly atmosphere would have been dispiriting to

[1] Read at the memorial meeting of the College of Physicians, April [illegible]

one less occupied in medical studies than Professor Flint. The ill-feeling manifested toward the college, and those connected with it, was apparently ignored by him.

During my stay in the hospital, among the subjects which occupied the attention of Professor Flint was what he designated "Variations of Pitch in Percussion and Respiratory Sounds," and his pocket note-book, in which he recorded his observations, was his constant companion. He contemplated sending an essay relating to this subject to the committee on prizes of the American Medical Association, at its next session, and the interest which he manifested in obtaining the material for the paper seemed to increase from day to day, and was noticed by all who followed him through the wards, and who were often asked to verify his observations. No one who saw the interest which he manifested in this subject, and his careful examination of cases, was surprised when the announcement came from a distant city, and appeared in the daily papers, that the annual prize of the United States Medical Association had been awarded to Austin Flint, of Buffalo.

Another subject which engaged his attention was the differentiation of typhus and typhoid fevers. A considerable number of Irish immigrants were admitted into the hospital having a malignant form of typhus fever, which they had contracted on shipboard, and when they reached Buffalo, on their westward journey, they were too sick to go farther. I have never met in this city, in a practice of thirty years, so severe and fatal a form of this disease, in which most of the patients presented a mottling of the surface like that of measles. Although sisters and nurses were stricken with it, some of them dying, each case was thoroughly examined, and the symptoms, and in fatal cases the lesions, were recorded. In due time a statistical paper containing the results of these examinations appeared from the pen of Professor Flint.

To me it was evident that the example of a life so devoted to the study of diseases had a very salutary effect upon the students of the college, many of whom, having no previous knowledge of medicine except what they had learned from the country practitioner and his obsolete books, and having chosen the profession of medicine simply as a means of livelihood, as one would learn a trade, appreciated for the first time the dignity and importance of the calling upon which they had entered, and saw that it merited the consecration of the entire life to its study and practice.

The life of Professor Flint during the thirty years which have elapsed since the period of which I have been writing is known to the profession. That he became the most prominent physician in America, and was honored throughout Great Britain as no other American physician has been, was due to his life-long and uninterrupted study of diseases. Nothing that arose in politics, or church, or society, diverted him from it. His investigation of any disease or subject in medicine which engaged his attention was thorough, and while he treated with proper consideration the views of others, and listened to suggestions from any source, even from students, the information on which he most relied he obtained at the bedside; and he did not express a positive opinion until he had made so many observations that he was certain of its correctness. Therefore no pupil of Hippocrates had greater faith in the teachings of the great master than those who were brought into intimate relation with Professor Flint had in his. Whenever he made a positive statement in regard to any medical subject, those acquainted with him knew that it was true, since it was based on a thorough investigation. In matters of doubt, he always gave prominence to facts which conflicted with theories which he believed to be true.

The success of Professor Flint in his profession seems to me to have been largely due to his practice of taking and preserving notes of cases at the bedside, which he began to do soon after he commenced the practice of medicine, and continued to do for many years, and I think, more or less, till the close of his life. By recording the history and symptoms of a case he made a more thorough examination of the patient, and in time he obtained an amount of statistics which were of the utmost value to him in his writings. Very few discoveries which threw light on the nature of diseases, or were likely to be beneficial in their treatment, escaped his notice. Only a few days before his death he questioned the writer in reference to intubation of the larynx in the treatment of croup, so successfully performed by Dr. O'Dwyer in the New York Foundling Asylum; and at an age when most physicians think of retiring from the active duties of life he continued to devote half an hour each day to the study of German, in order that he might read German medical literature with more facility.

The Sydenham of the nineteenth century is taken from us, but his great work, his "Treatise on the Principles and Practice of Medicine," the revision of which was his last professional labor, remains with us. No book has had a more salutary effect on the medical profession in America than this, for while it is extensively read by physicians in the cities, as well as in country towns, it contains the most recent opinions which have been established by clinical observations and experiments, while the treatment which it recommends is in a high degree conservative, and is that which is accepted by the most skilful and experienced practitioners. The writings of the great teachers in our profession have sometimes, as we know, done harm, more, perhaps, than benefit, like those of Broussais; and even in the writings of so recent and practical a physician as Trousseau there are passages which we now wish had never been penned; but in the treatise of Professor Flint, so painstaking and thorough was he in the investigation of any subject on which he wrote, that, in my opinion, very few sentences can be found in the eleven hundred pages that do not possess enduring worth.

I recently heard him say of the "System of Surgery," written by his intimate friend, the late Professor Gross, that even if its modes of treatment should become obsolete, it would always be valuable as showing the status of surgery in the nineteenth century. A similar remark might be made of Flint's treatise, that it will always possess value as showing the state of medicine in the last half of the nineteenth century, as that of Sir Thomas Watson does in the first half, but this is too low an estimate of so valuable a book. No one can read Flint's treatise without recognizing in it an enduring basis, so that with the additions made to it, from time to time, of discoveries, as they occur in medicine, it will probably continue to be one of the text-books consulted for information and guidance long after the present generation have passed away.

Rabies and Muzzles.—M. Gibier writes to the Académie de Médecine that there has not been seen a single case of rabies for three years at the Imperial Veterinary School of Berlin, although there are as many dogs in Berlin as elsewhere and they are always muzzled. During two weeks in November nineteen dogs suffering from rabies were brought to the veterinary school of Lyons, a city where the practice of muzzling dogs is not in vogue. The *Lyon Médical* observes that this does not bear out the assertion of some fanatical cynophiles that the wearing of muzzles is the cause of rabies.

Bacteriotherapy.—Dr. Salama reports another case of advanced pulmonary phthisis treated according to Cantani's method, by inhalations of bacterium termo. Within five days an improvement was noted, the fever was less pronounced, and the expectoration was diminished in quantity, and contained a smaller number of tubercle bacilli. In two weeks the bacilli had wholly disappeared from the sputa, and the patient began to increase in weight and in general health.

REMARKS ON LATERAL CURVATURE, WITH SPECIAL REFERENCE TO ITS OCCURRENCE IN CHILDREN.[1]

BY SAMUEL KETCH, M.D.,

In the whole range of that department of medicine now specialized as Orthopædic Surgery there is no subject which has attracted so much attention from those engaged in the practice of it as has the study of the problems connected with rotary lateral curvature of the spine. Much has been written in defence of the various theories which have been advanced at different times concerning its etiology, pathology, and treatment, and yet to-day it remains as mysterious in its origin, as complex in its manifestations, and as resistant to treatment as ever. It is but natural, therefore, that in the study of this perplexing disease many ideas which have been advanced should have been received, then rejected, and for the time forgotten, until again presented in a newer garb and made prominent by some unusually zealous advocate. In this way many truths have been transmitted, these being the crystallization, so to speak, of the various theories which have been held from time to time, and in the same way errors have been perpetuated, and of these none has been more commented on than puberty in its relation as a causative agent to the disease in question.

It is not the object of the present paper to discuss the whole subject of rotary lateral curvature of the spine, but believing that the isolated study of certain points connected with it will do much to place our collective knowledge on a surer and more scientific basis, it will be the aim here only to investigate the relations of age and sex to this deformity, and thus, if possible, arrive at conclusions, supported by statistics, concerning the period of life at which we may first look for its manifestations. In watching the progress of a case of rotary lateral curvature one cannot fail to be impressed by the very slow, but nevertheless constant and progressive character of the disease. Its insidious nature, both in onset and course, are among its most striking characteristics, and it is against this element of progression that we have mostly to contend. Whatever the primary cause of the disease may be, it must be something which is remote in its origin and constant in its action, and what are ordinarily described as causes are frequently only effects of it. Thus there must be something which acts long before these effects are noticed, and we must look beyond these to find the causation of an idiopathic rotary lateral curvature. Whilst we fully recognize the difficulty of obtaining pathological evidences early in the disease, owing to the fact that it is not one which ends in death *per se*, we believe that the study of analogous deformities in other parts of the body is beginning to show us the right path.

The formidable deformity which most cases of rotary lateral curvature present to us when first seen, precludes the possibility of a rapid development of the disease, months and years being occupied in its advance. Of the so-called cases of "pernicious" or rapid lateral curvatures, I have seen no examples, and when they occur I am sure they are connected with acute coincident troubles. Yet, as will hereafter be shown, the mass of authorities speak of the disease as being for the greater part connected with a certain period of life, namely, *the age of puberty*. That the cases most frequently present themselves to us at this age there can be no reasonable doubt, but the explanation of this fact can be made apparent in many ways. On close questioning, the histories of most of the cases I have developed show that the parents or attendants have noticed something peculiar about the patient for a long time, this peculiarity being shown either by a slight irregularity of form or of the position of the patient in sitting or standing. This, however, on account of the painless character of the affection, has not given rise to anxiety, or been thought of sufficient importance to demand more than passing attention, either being entirely ignored or more often ascribed to habit. Arrived at puberty, however, when the question of form and dress becomes a matter of greater importance, especially in females, in whom the majority of cases occur, the patients are subjected to a more rigorous examination. This at once reveals the presence of a curvature, and usually of a character far advanced. Being discovered at this time it has been assumed that there must be a causative connection between this epoch and the disease. While we cannot deny that the conditions at this time are most favorable to the increase of a curvature, as indeed they are of any pathological condition which may be present in a latent form, and which may be well exemplified, for instance, by the apparently sudden invasion of phthisis at this period, it does not follow that this is the time of the origin of the trouble, but would rather tend to prove that the general efflorescence was the means of bringing the disease into more active participation. It has been my experience to see very few cases of lateral curvature at this age where the symptoms would indicate that they were of recent origin, and where they occurred the curves were mostly of the character termed functional, due to relaxation of the long spinal muscles, rather than a typical rotatory curvature. Thus it becomes a matter of great importance, in determining the time of origin in rotary lateral curvature, that the first appearance of the symptoms should be carefully ascertained, this being our criterion, rather than the age at which the curvature is first discovered. It cannot have failed, in this connection, to have struck those familiar with this class of cases, what a large rôle the dressmaker plays in their discovery. It is among the most frequent answers given to my inquiry as to the duration of the trouble, to be told, "Only a few weeks," and on asking for the first symptoms noticed, to be told that the dressmaker had called attention to the high shoulder and prominent hip.

Another remarkable thing is the complacency with which the disease itself is usually regarded by the parents, a fatal idea prevailing that the patient will "grow out of it," and which is not uncommon in regard to certain deformities where the element of pain is either very slight or totally absent. Should the disease have been attended with the pain consequent on an inflammatory lesion of the spine, such as occurs in Pott's disease, the many cases of terrible deformity seen in lateral curvature would probably occur less often as a reproach to the orthopædic surgeon. In the painless and insidious character of the affection lies another obstacle to the early discovery of the disease, and in these elements are comprised the greatest danger to the patient. The very earliest indications of the disease, namely, those which are shown by some peculiarity of posture, are the ones which, being ascribed to habit, are undoubtedly the efforts of nature to equalize the forces acting on the spine in order to preserve the integrity of its curves, and accomplished through the action of its muscles. Here the patient endeavors to place himself in that position where it is most convenient for their perverted action; but although, like the reflex muscular spasm of joint disease, it is in a measure protective, it is so to the ultimate disadvantage of the spinal column, unless relieved by suitable treatment. This habit, which has been assigned a prominent etiological position, is in reality a result of the disease, and not a cause of it, and I doubt exceedingly whether any habit, however long continued, will, unaided by other factors, do more than result in a functional non-rotary curvature. The proper appreciation of these early symptoms, and an immediate examination of the spine would, at this period, undoubtedly give indi-

[1] Read before the Orthopædic Section of the Academy of Medicine, January 22, 1886.

cations of danger; and as in joint and Pott's disease, give the surgeon the best opportunity for checking its further progress.

For the past eight years my attention has been called to the occurrence of many cases of lateral curvature in children presenting themselves at the New York Orthopædic Dispensary, and in most of them I found all the symptoms of advanced scoliosis. The histories of these cases, as a rule, are negative. Nothing irregular has occurred at birth; hereditary histories, with a few exceptions, showed no especial peculiarities of form or of deformities in parents or relatives; the patients have generally been healthy children, and at time of examination were in good general condition. Various causes, as stated by parents, were assigned, these being for the greater number unknown, and in others were attributed to accidents or illness. The local symptoms referable to the deformity were identical with those observed in adolescent cases. They had the prominent scapula, the protuberant hip, and the well-marked rotation of the vertebræ observed at a later period of life.

In none of the special works on lateral curvature of the spine which I have been able to consult do I find more than the scantiest mention made of this disease occurring in childhood, and although cases not infrequently come under the notice of the orthopædic surgeon, they would seem rather to be regarded as rarities than as of frequent occurrence, or as constituting a large and important class of these cases. Thus, Adams, in his "Lectures on Curvature of the Spine," states: "But as to the age at which severe cases of lateral curvature most frequently commence, I have no hesitation in stating that, if *we omit those* which occur in infancy and early childhood, say before five years of age, which are generally of an hereditary character, the next class—a very numerous one—are those which most frequently commence between the ages of seven and twelve years. These cases have also, not uncommonly, a history of hereditary tendency, but in many instances this cannot be traced, and the constitutional cause *seems* to consist in a strumous diathesis. Consumption is very frequently to be traced in the family history, and the death of the mother by this disease is of common occurrence. Whether the cases included in this class are numerically equal to, or exceed those in the next class to which I shall allude, viz., such as occur between the ages of twelve and sixteen years, I am unable to say from statistical data; but, speaking from private practice, I think they are at least as frequent, if not more so. Still keeping below the age at which stiff stays are commonly worn, or tight-lacing indulged in, we have the class of cases of lateral curvature in quickly growing girls between the ages of twelve and sixteen years. *This is assumed to be the typical and popular class of cases by the great majority of authors on lateral curvature.*"

Alexander Shaw, in his article on "Lateral Curvature of the Spine," published in Holme's "System of Surgery," says: "Lateral curvature is incident to youth. Commencing insidiously, without warning from bad health, it can only be stated generally that the first appearance of it may be looked for at about ten or fourteen years of age." And again: "The age at which the deformity commences coincides with that at which a notable change takes place both in the physical and moral constitution of a female."

Bauer, in his work on "Orthopædic Surgery," 1868, speaking of lateral curvature, remarks: "Scoliosis originates most usually at the time of puberty, and in young ladies whose sexual development is protracted; whose menstruation is either imperfect or has not yet made its appearance; whose condition is feeble from rapid growth and confinement, and whose spine is endowed with an unusual degree of flexibility." Furthermore he says: "In summing up these facts, and in excluding from consideration traumatic and dyscrasic causes, we are reduced to a few points, which proves that *scoliosis bears a close connection to a certain age, to the female sex, its evolution, and a certain general condition of the system and the spine.*"

Davis, in writing on the subject of "Conservative Surgery," 1867, says: "There are some facts in the preceding pages that have not been fully considered, and others that have not even been noticed by writers upon this subject, which we think are worthy of attention. We refer particularly to facts in connection with the common form of lateral curvature, commencing about the period of puberty, always, we believe, in connection with it. In the first place, lateral curvature of any form can almost be said to be a deformity confined exclusively to females. The relative number is so great as to render us unable to make any approximation to the proportion, and when it does occur in males it is attributable either to some mechanical cause or to some defect in the nervous system. Therefore, we may say that lateral curvature is a disease peculiar to females. We have said the period of its development is at puberty."

Brodhurst ("Lectures on Orthopædic Surgery," 1865), states that "lateral curvature is the most common form of spinal curvature. It occurs more frequently in the female than in the male sex; it seldom commences after the age of puberty, and it does not commonly occur as a primary affection."

Noble Smith ("The Surgery of Deformities," 1882) says: "Lateral curvature commences most frequently at about the period of puberty, between the tenth and sixteenth years of age, but it frequently occurs at later or earlier periods of life."

Neither in his work ("Orthopædic Surgery," etc., 1879,) nor in his "Spine and Spinal Diseases," does Dr. Sayre make any special reference to this point.

Taylor ("The Pathology and Treatment of Lateral Curvature of the Spine," 1868) remarks: "It is at the age of purberty when the legitimate lateral curvature is formed." He says, furthermore, in speaking of treatment: "It will be remembered that we found that the most common form of lateral curvature occurs only at a certain period of existence; that this period embraces about three years, more or less, about the age of puberty; commencing a year or two before, and the liability continuing not later than the sixteenth year, and often ending much earlier, after which time the formation of the lateral curvature is impossible."

Shaffer, in "A Lecture on Lateral Curvature of the Spine," 1881, states as follows: "It is known, for instance, that lateral curvature develops most frequently in females between the ages of twelve and eighteen years; that it presents as a deformity involving the right side more frequently than the left, and that a peculiar nervous state, called hysterical or emotional, almost always accompanies its development. But the relation of age to this particular lesion is not at all peculiar—almost all chronic diseases have a similar history in this regard; poliomyelitis is rarely anything else than a disease of infancy, joint and spinal diseases are typical lesions of childhood, and lateral curvature develops much more frequently in children and in boys than is generally supposed—with sufficient frequency, anyway, to warrant us in saying that its etiology has nothing to do with either age or sex. It is fair, however, to state that the conditions that finally produce lateral curvature are more likely to exist in girls who are just approaching or who have just passed puberty; but there are many conditions present, just at this particular time, which may have no direct relation either to the sexual development or to the strictly physiological processes then occurring. If typical lateral curvature can exist and progress in babies of six months, or in boys of eight years, or in young men of eighteen, we must take a much broader etiological view than has heretotore been held.

M. Eulenberg ("Die seitlichen Rückgrats-Verkrümmungen"), 1876, Berlin, has given statistics regarding

the age at which scoliosis originates, his researches covering 1,000 cases. The results are as follows:

	Cases.		Per cent.
Before the second year	5	=	0.50
Between the first and second year	21	=	2.10
" " second and third year	9	=	0.90
" " third and fourth year	14	=	1.40
" " fifth and sixth year	3	=	0.30
" " sixth and seventh year	23	=	2.30

" " eighth and fourteenth year	15	=	1.50
" " fourteenth and twentieth year.	28	=	2.80
" " twentieth and thirtieth year...	7	=	0.70

He also gives the results of an analysis of 500 cases of rachitis scoliosis, as follows:

	Cases.		Per cent.
From birth to the first year	58	=	11.60
Between the first and second year	272	=	54.40
" " second and third year	124	=	24.08
" " third and fourth year	23	=	4.06
" " fourth and fifth year	10	=	2.00
" " fifth and sixth year	7	=	1.04

Eulenberg regards congenital scoliosis as of the rarest occurrence, only having been noticed in connection with congenital rachitis (Malgaigne) or anenkephalics (Depaul). On the contrary, he considers heredity as a marked factor, and that in at least twenty-five per cent., and possibly more, of the cases it is due to this cause. Hueter in his "Gelenkrankheiten," Leipzig, 1877, says: "The disease occurs most frequently in females, and seldom happens before the sixth year. The greatest number of scolioses originate from the sixth to the tenth year, although it is not unusual for them to occur between the tenth and fifteenth year. They rarely originate in the latter years of growth, those occurring at this period having an entirely different etiology.

Vogt, in the "Moderne Orthopädik," 1883, speaks of the disease, when occurring in children, of being principally rachitic in origin.

Dubrueil simply remarks, in his "Eléments d'Orthopédie," 1882, that it is generally toward the age of twelve that scoliosis usually develops.

De Saint-Germain ("Chirurgie Orthopédique") remarks: "It is usually the mother who first notices that her daughter, aged from ten to fourteen years, has one shoulder prominent.

Enough authorities have been quoted in the preceding pages to show the almost universal consensus of opinion regarding puberty as a most important etiological factor, and as the most frequent time for the occurrence of lateral curvature. The exceptions to this have been found in the writings of Adams, Eulenberg, Hueter, and Shaffer.

In order to arrive at proper conclusions concerning the age at which lateral curvature of the spine is most frequently first observed, I have, with the valuable assistance of Dr. Thomas L. Stedman, collected 229 cases, taken from the records of the New York Orthopædic Dispensary, and representing those applying for relief during the years 1878 to 1885, inclusive. The cases selected are only those where the typical symptom of rotation was present. Before giving the results of the analysis made of these cases, I wish to explain that I have divided them into three classes.

1. Those where the deformity was first observed from birth to the twelfth year, or the age of childhood.

2. Those where the deformity was first observed from the twelfth to the eighteenth year, or the age of puberty.

3. Those where the deformity was first observed from the eighteenth year and upward, or the age of complete development.

Of the 229 cases analyzed, 189 occurred in females and 40 in males. The youngest case observed was two weeks old, the oldest, sixty years.

During the first period, or age of childhood, the deformity occurred in 120 cases. Of these 120 cases, 42 occurred in the first seven years of existence; 26 cases being in females and 16 in males. From the seventh to the twelfth year there occurred 78 cases, of which 64 were in females and 14 in males; the total per cent. of cases in this period to the whole number being about fifty-two. During the second period, that of puberty, 94 cases were recorded, 80 occurring in females and 14 in males, being about forty-one per cent. of all the cases collected. In the third period, from eighteen years and upward, 9 cases occurred, 6 in females and 3 in males, or about three and a half per cent.

In 6 cases it has not been stated at what age the deformity was first observed, all of these occurring in females, and constituting about two and a half per cent.

To recapitulate briefly:

	Cases.		Per cent.
During first period	120	=	52
" second "	94	=	41
" third "	9	=	3.5
Age not stated	6	=	2.5

The whole proportion of females to males was about four and one-half to one.

I wish to call attention to the fact that in analyzing these cases I have been particular to ascertain the age at which the curvature was first observed, and not, as has been frequently done, the age at which the case presents for examination. From the nature of the disease previously alluded to, it is fair to conclude that even at this time the disease had been present for a long period. From the results of the foregoing analysis I have arrived at the following conclusions:

1. That rotary lateral curvature is principally a disease of childhood, and may be either congenital or acquired.

2. That puberty, except as a concomitant occurrence, which may by its attendant circumstances increase it or bring it into unusual prominence, has no direct causative influence.

3. That lateral curvature should be looked for early in life, and as a factor in treatment the early inspection of children's spines becomes most important toward the prevention of the deformity.

RECENT MEDICO-LEGAL CASES.

By HENRY A. RILEY, ESQ.,

New York.

A CURIOUS insurance case is reported in the Supreme Court of the Territory of New Mexico. The Travellers' Insurance Company was defending a suit on an accident policy where the insured person was injured by a rupture of the tympanum of the ear, caused by diving while in bathing. The plaintiff testified that the ear was injured by the external violence of the water, and that the injury was really an accident such as would make the company liable. The defendants, on the contrary, asserted that the harm to the ear came from coughing, or at most only from contact with water by diving in the usual and ordinary course of common bathers. The judge decided that the evidence warranted the conclusion that the bather leaped from a plank for the purpose of diving into deep water, and said that "a slight accidental turn of the body while descending into the sea might very easily bring his ear in contact with the water in such manner that the force of his passage through it would create the injury." Consequently the company had to pay. It would seem that an insurance company which pretends to insure against accidents would not be able to do much business if it makes a practice of fighting claims apparently as clearly accidents as this one.

A testator who recently died in Brooklyn made some curious mistakes in his will. He left $2,000 each to a number of charitable institutions, but as the titles of the societies were wrong, the executors declined to pay the bequests until directed to do so by the court.

The matter was referred to a lawyer for examination, and he now reports that the bequest to the Female Em-

ployment Society was intended for the "Brooklyn Female Employment Society." The bequest to the Half Orphan Asylum on Atlantic Street was intended for the "Orphan Asylum of the City of Brooklyn." The bequest to the Graham Institute was intended for the "Brooklyn Society for the Relief of Respectable Aged and Indigent Females." The bequest for the Brooklyn Industrial School was intended for the "Brooklyn Industrial School Association and Home for Destitute Children."

The referee having reported in favor of paying the bequests to the institutions which seemed really intended to be benefited by the will, the court has directed this to be done.

The estate has suffered pecuniarily by the neglect to have the will carefully drawn, and the moral is an evident one.

Washington is now the headquarters for a stubborn fight between the oleomargarine and anti-oleomargarine men. The measure, which is proposed by the farmer element, is a tax upon all oleomargarine exported. This was a mode of attack thought to be certainly constitutional, and Congress has without question jurisdiction over general commerce. The outcome is quite uncertain, as thus far there has not been much done except skirmishing along the line. In Connecticut the farmers have influence enough to get a law through the House which will make the persons using the imitation quite uncomfortable. All stores selling oleomargarine must have signs plainly stating the fact; hotels, restaurants, and boarding-houses are required to place notices where all guests can see them. If a baker uses the imitation or sends a wagon about with his wares he must put a sign on the wagon with the legend "Oleomargarine Used Here." The penalty is a fine of from $5 to $50, or imprisonment for thirty days.

The authorities of Stockton, Cal., have been trying the health dodge to drive out the Chinese, but have found the Circuit Court of the United States in the way. An ordinance had been passed to regulate the laundry business, which prescribed certain parts of the city where the business could be carried on, and certain other portions where it could not. The forbidden portions turned out to be the habitable parts of the city, and the area where the business was to be carried on without hinderance proved to be uninhabitable marshes. The court said that such an ordinance meant simply destruction to the whole laundry business, and was so intended. It was not proper to regulate a business in such a way as to inevitably destroy it. The great objection, however, was that it was unconstitutional; the law of the land permitted the carrying on of lawful occupations, and as the regulation might affect Americans as well as Chinese, it was void. The meaning of the ordinance, Judge Sawyer said, was "The Chinese must go," but they could not be forced out in an illegal way. This is not the first instance where the courts have stood out honorably against the unjust persecution of the Chinese.

Remarkable Fecundity.—Dr. F. W. Putnam, of Binghamton, N. Y., writes: "July 21, 1884, I delivered Mrs. H. B——, a German lady forty years of age, and married twenty-two years, of her twentieth child. February 16, 1886, I delivered her of her twenty-first child. All have been single births except one pair of twins."

Cancer of the Stomach.—Many remedies have been proposed for the relief of the pains of carcinoma of the stomach, among others chloroform and cocaine. The following is recommended as of special efficacy by Germain Sée: Tincture of hyoscyamus and tincture of conium, each two drachms; tincture of gentium, one drachm; oil of anise, two drachms. Of this from ten to thirty drops may be taken after each meal.—*La Riforma Medica.*

Clinical Department.

TRYPSIN IN DIPHTHERIA.

Dr. E. W. Saunders, of St. Louis, Mo., writes: "I wish to call the attention of the members of the profession who have not used the new remedy, trypsin, to its efficacy in dissolving diphtheritic membrane. In every case in which I have tried it, all the membrane in sight was dissolved in less than one day, and in one case of extensive formation in the fauces, and also in the larynx, it certainly retarded the fatal issue. The symptoms of stenosis were only partially relieved, owing, no doubt, to the fact that the solution was not effectually applied to the larynx, and to the additional fact that the œdema of the glottis persisted. Tracheotomy was not urged, as the systemic infection was profound. The solution which I have used is of the strength of fifteen grains to the tablespoonful of water, with five grains of bicarbonate of soda added. This is sprayed upon the parts once every half-hour until the membrane disappears. The solution should be kept in a cool place."

SCARLATINA IN UTERO.

Dr. Wilson Saffin, of Carthage, O., reports the following case: A lady of good general health, who had had scarlatina when young, was delivered of a male child, labor being normal and of short duration. During the two weeks preceding delivery she was in constant attendance upon her older child, who was suffering from malignant scarlet fever, and who died three days after her confinement. During the first week of this child's illness the mother contracted a very sore throat, characterized by intense hyperæmia and involvement of the submaxillary glands. Immediately after delivery, upon examination of the child, the characteristic rash of scarlatina was observed. The disease was well marked, and ran a course of nine days. Desquamation occurred on the fifth day, and was as natural and well marked in large and small flakes as in any other and older child. The temperature ran from 100° to 104°, and was highest on the third day of life. Considerable nausea and diarrhœa were manifested on the third and fourth days, but no other symptoms than those mentioned presented themselves. The mother and child both made a good recovery, although the woman was confined in the same room in which her other child died. Dr. Saffin diagnosed the case as one of scarlatina in utero, as the rash was fully developed at birth.

VACCINATION IN PULMONARY PHTHISIS.

Dr. John W. Taylor, of Crawfordsville, Ind., writes that some years ago his brother, Dr. H. W. Taylor, conceived the idea of vaccination in the treatment of pulmonary phthisis. A case presented itself, showing cough, night-sweats, progressive emaciation, and the physical signs of tubercular lung affection. The patient was vaccinated over the diseased lung, and it "took" handsomely, and very decided relief followed. The patient was now vaccinated repeatedly during the next two years, and each time there was improvement, until finally the virus failed to make any impression on his system. His gradual decline then began, and he died in a year's time. The benefit he derived from these repeated vaccinations was much greater than that obtained from any other procedure. It was subsequently tried upon a number of similar cases, and every time that the vaccination "took" there was marked improvement, much more, Dr. Taylor thinks, than could be accounted for on the theory of simple counter-irritation. The writer suggests that this plan be tried in hospital practice, in order to ascertain how much value it really possesses. Owing to various causes no experiments on a large scale could be made by him or his brother.

MORPHINE IN THE TREATMENT OF CONVULSIONS OF INFANTS.

Dr. George T. Fanning, of Stony Brook, N. Y., reports the two following cases of convulsions in infants, in which morphine was given with ultimate good results. The first case was that of a girl, two years of age, who, when first seen, had been in rigid convulsions for about two hours. Potassium bromide and belladonna were given at short intervals for nearly three hours without relief, when it was determined to try morphine, and a dose of one-eighth of a grain was accordingly given. In about half an hour the convulsions stopped, and the child stopped breathing at the same time. Artificial respiration was at once begun, and kept up for nearly an hour, at the end of which time natural breathing began again. The second case occurred in a boy, two and a half years old. Supposing the convulsions to be due to intestinal irritation, Dr. Fanning ordered an emetic and an enema, and gave chloroform to relax spasm. The convulsions ceased, and the writer went away, but was recalled in about an hour, the messenger stating that the child was worse than ever. He was found in a very rigid condition, with one pupil widely dilated and the other contracted. After an unsuccessful trial of chloroform, one-thirtieth of a grain of morphine was given hypodermically, and in an hour one-sixteenth of a grain more. The pupils both became contracted, the breathing was slow and stertorous, but the convulsions continued on one side. The chloroform inhalations were continued for about two hours, when improvement occured very slowly, and the child finally recovered.

A CARBUNCLE CURED BY A GONORRHŒA.

Dr. F. N. Smith, of Allentown, N. Y., writes: "I had been treating a young man for boils and carbuncles some ten days, when, on one day, a large carbuncle on the back of the neck was just on its way toward maturation, acutely painful, and preventing all work—my patient was a railroad-bridge builder. The next day, very early in the morning, he came to me, saying that his carbuncle was about well, but that he had a private disease, just showing itself that morning, and would like that attended to now. On examination I found a well-marked case of gonorrhœa. He had no more trouble with carbuncles from that day; the specific disease passed away in due time. There is no doubt that the occurrence of the gonorrhœa had the effect of arresting at once the progress of the carbuncular inflammation."

UNUSUAL SOURCES OF INFECTION IN THE PUERPERAL STATE.

Dr. J. J. Smith, of Boston, Mass., sends us a report of two cases of infection in puerperal women, which he regards as of interest, as illustrating the sometimes unsuspected sources from which such infection may come. The first case was that of a woman who was confined in a room directly over one in which two children were sick with measles. The windows in both rooms were kept open, while the temperature was maintained at 70° by means of a fire. The woman was also instructed to wash out the vagina daily with a one per cent. solution of carbolic acid. On the morning of the third day she awoke with a severe headache, and soon had a chill lasting half an hour; the pulse was 128, and the temperature 104°. The lochia disappeared, profuse sweating occurred, and no milk was secreted. These symptoms continued for a few days, and subsided after the children had recovered from the measles. The second case was one of normal labor, with an exceptionally good convalescence. Some eleven days afterward Dr. Smith was called to vaccinate some other members of the family, and, on entering the room in which his former patient was, noticed a very strong and disagreeable odor. On inquiry, he learned that a drain in the yard had just been opened. He advised that the rear window be closed, and ventilation be secured from the front of the house. This advice was at once acted upon. But the writer was called the next morning, and was informed that the patient had a very severe headache. She had soon after a chill, lasting nearly an hour; the pulse was 120, and the temperature 103⅘°. There was some sweating, and the milk was reduced nearly one-half in amount. After a few days, during which time the drain had been closed, these symptoms gradually wore away and convalescence proceeded uninterruptedly. There was no fœtor to the lochia at any time in either of these cases. Dr. Smith does not assert that infection certainly occurred either from the measles or from the sewer-gas, but he regards it as very probable, since there were no lacerations, nor was there any evidence of decomposing blood-clots or of fragments of decomposing placenta in the uterus.

Progress of Medical Science.

Non-Operative Treatment of Dupuytren's Contraction.—Dr. Costilhes has collected a number of cases of contraction of the palmar fascia, from a study of which he concludes that, though local causes may often play an important part in the production of this affection, the prime and predisposing cause is to be found in a general dyscrasia, such as rheumatism, gout, diabetes, lead-poisoning, and perhaps also syphilis. Far from being usually progressive, as is commonly supposed, the disease, he maintains, is often stationary, and may even show periods of spontaneous improvement, and a purely medical treatment is frequently productive of excellent results. The author relates some cases in which a cure was obtained by the local treatment recommended by Vulpian. This consists in the prolonged use of the following ointment: Tincture of iodine, one-half drachm; iodide of potassium, two and a half drachms; lard or vaseline, five drachms. This ointment should be applied liberally over the entire surface of the palm, and over this is placed a double layer of wadding retained by a few turns of a bandage. The application is removed once a day until the epidermis of the palm is entirely exfoliated. The results are sometimes very rapid, so that a notable improvement may be obtained within a fortnight. To this treatment may be added with advantage, in certain cases, the internal exhibition of the iodides and methodical massage of the affected parts.—*Giornale Internazionale delle Scienze Mediche*, January, 1886.

Albuminuria in Strangulated Hernia.—Dr. J. Englisch found albuminuria present in thirty-two out of fifty-four cases of strangulated hernia. It was manifested almost immediately upon the occurrence of strangulation, and the greater the degree of the latter the more pronounced was the albuminuria. There was no albumin in the urine in the cases observed of strangulated hernia of the omentum or epiploic appendages, nor was there any in simple inflammation of the hernial sac. The albuminuria was very marked in gangrene of the intestine, and after the release of the strangulated gut by operation the albumin usually became gradually diminished in quantity. In fatal cases of strangulation the albuminuria was most marked, and the quantity of urine became less as that of the albumin increased. The author believes that death in certain cases of strangulated hernia, in which no sufficient explanation for it can be found post-mortem, is often due to the existence of albuminuria. He deduces a practical conclusion from his studies, which is, that when albuminuria appears in conjunction with strangulated hernia, no attempts at taxis should be made, but an operation should be resorted to at once to free the imprisoned intestine. —*Gazzetta Medica Italiana Lombardia*, February 6, 1886.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

INTUBATION OF THE LARYNX.

THE question of operation in croup or laryngeal diphtheria may be said to be yet *sub judice*, although of late years the tide of professional opinion has been setting strongly toward the side of surgical interference. And although authorities are now almost unanimous in advising that tracheotomy be employed at one time or another in membranous croup rather than to let the child die from strangulation, they are by no means at one in counselling an early operation, some maintaining that it should be undertaken immediately upon the appearance of the first sign of stenosis, others averring that it is a desperate measure which is justifiable only when all other means have been tried in vain. And practitioners in general are still very loath to even suggest what they are wont to regard as an heroic measure and one of little practical utility. There is much reason for this. The parents and friends are naturally distressed at the thought of an operation, and, unless they can be assured of its success, will often refuse their assent to its performance. Again, tracheotomy is by no means the simple procedure which some of its enthusiastic advocates, with a greater fund of theory than of practical experience to draw upon, would assume. Tracheotomy performed on the living subject, especially a child, struggling for air, with the larynx rising and falling at each labored respiration, and with the blood pouring from the turgid veins to obscure the delicate field of operation, is one of the difficult tasks of the surgeon, and, taking into consideration the problematical chances of final success, is one which he assumes with no light heart. It is, therefore, not surprising that the operation has been slow in gaining recognition as a justifiable therapeutical measure despite the fact that many lives have been undeniably saved by its timely performance. And if any more simple operation could be devised which could be shown to be of at least equal value it would be welcomed.

We referred recently in these columns to the method of intubation of the larynx first proposed and practised by Dr. Joseph O'Dwyer, of this city. This method does away with the use of cutting instruments, and consists simply in the insertion of a tube of peculiar shape between the vocal cords, thus permitting of the passage of air into the trachea. Dr. O'Dwyer's experiments have been conducted very unostentatiously, and it is only through some very recent publications in the journals of New York and Chicago more particularly, that we have been able to obtain any data upon which to base an estimate of the merits of the procedure. Every new therapeutical measure must be judged by its results, and if on extended trial it cannot prove that it is better than some older and tried remedy, it deserves to, and surely will, fall into oblivion.

The largest number of reported cases of intubation of the larynx for pseudo-membranous laryngitis have been performed by Dr. F. E. Waxham, of Chicago,[1] who has had 17 cases with 8 recoveries; Dr. Dillon Brown[2] reports 15 cases with 4 recoveries; Dr. E. F. Ingalls,[3] 2 cases, both fatal; and Dr. W. P. Northrup,[4] one successful case. In addition to these, Dr. A. B. Strong[5] has employed the method with success in one case of acute catarrhal laryngitis.

These are all the published statistics which we have been able to discover in a somewhat hasty search, and, excluding the case of catarrhal laryngitis, we have 35 operations with 13 recoveries, or slightly over 37 per cent., certainly a very favorable showing, when we consider that nearly one-half of the cases were foundlings, and many of them infants.

If now we turn to the results of tracheotomy we find a smaller percentage of recoveries, taking the statistics of hospital and private practice together, as has been done in the case of intubation. Gay[6] states that of 206 cases of tracheotomy performed for croup in the Boston City Hospital during twenty years there were 65 recoveries, about 31 per cent., and in his own practice he has had 29 recoveries in 86 operations, nearly 34 per cent. Of 77 cases operated upon during the year 1885 in the same institution, Lovett[7] states that 20, or nearly 26 per cent., recovered. These results are not very different from those formulated by Agnew[8] in a study of upward of 11,000 cases, and we may therefore assume the average percentage of recoveries after tracheotomy to be not far from 30, although Solis-Cohen[9] is disposed to regard the operation in a less favorable light, notwithstanding his own brilliant series of successes.

We thus find that Dr. O'Dwyer's method already compares very favorably with tracheotomy as regards the saving of life, while certainly, to consider it from an æsthetic point of view, it is much to be preferred. It is, however, too soon to pronounce absolutely upon its merits, for the figures are too small and the operators too few to serve as anything more than an encouragement for further trials. It is only after a method has become in a measure popularized, and the number of cases has mounted into the hundreds, that we can form an adequate judgment of its worth. But if intubation of the larynx proves itself to be as valuable as these first essays would lead us to hope, it will be accounted one of the great advances in this age of medical discoveries, and we may only wish that such will be its fate.

BACTERIA VERSUS LEUCOMAINES.

NOTWITHSTANDING the rapid spread and very general acceptance of the theory of the bacterial origin of infectious diseases, there are yet many who are still unconvinced of the truth of the new doctrines, and not a few who are absolutely incredulous. The theory is certainly a very plausible one, and seems to be borne out by many incontestable clinical and histological facts; and its opponents have been hampered by their inability to formulate any other theory, by which the phenomena of contagion could be explained, which could rest upon tangible and indisputable facts. The results of some recent investigations of M. Armand Gautier and others have, apparently, at last given them a rock, or at least a raft, upon which they can rest their cannon and fire their shots into the enemy's fleet without themselves being swamped by the recoil. And we may now see the war begin in earnest.

The Academy of Medicine of Paris was the scene of the first effective battle. It was opened by M. Gautier, who presented a paper embodying the results of his investigations concerning the animal alkaloids, ptomaines, and leucomaines, found respectively in dead and in living tissues, and which were capable of inducing toxic symptoms similar to those caused by many of the vegetable alkaloids. One of these leucomaines, he stated, had been isolated from the tissues of the spleen and pancreas by Kossel, of Berlin. It was formed in the living organism by the destructive decomposition of a complex albuminoid substance known as nuclein, constituting the greater part of cell nuclei, and was isomeric with hydrocyanic acid, its formula being $C_3 H_3 N_3$. Morelle had also discovered in the spleen a second alkaloid, which had been found, by experiments on the lower animals, to be a motor paralyzer and to produce effects analogous to those caused by muscarine and digitalin. He also stated that, in addition to these alkaloids, there are other non-crystallizable bodies, formed in the living organism as a result of vital processes, which are even more poisonous than the leucomaines and are capable of producing an intense auto-infection. The poisoning from these substances differs from that caused by leucomaines in that it is accompanied by fever.

M. Peter, who has always been one of the most active opponents of bacteriologists in general, and of Pasteur in particular, hailed this communication as marking a new era in medicine. This discovery, he exclaimed, freed scientific medicine from the thraldom of bacteria; the phenomena of disease were the result of vital actions, were produced within the organism itself by living and active cells, with which microbes had nothing to do. All through life, he said, there is a continual circle of change, new elements are brought in, old ones are removed, and the "cadaveric portion," the result of the wear and tear of the tissues, is eliminated. Whenever the production of these effete matters is in excess of the powers of the emunctories to get rid of them, whether through increased waste of the tissues or decreased power of elimination or destruction, the phenomena of disease arise. The disease so produced will vary, according to the greater or less accumulation of the toxic material, all the way between typhus and a mild ephemeral fever. Cholera, too, can be more easily explained as a poisoning by ptomaines or leucomaines than as the result of a secretion from the comma-bacillus. The speaker went much further than M. Gautier, who admitted that there were certain diseases, such as the eruptive fevers, in which one must recognize the action of a contagious germ coming from without.

M. Cornil replied at some length to this arraignment of the bacteriologists, and maintained that M. Peter had failed to offer any satisfactory substitute for the prevailing theory of contagion. He said that a disturbance of equilibrium between the different parts of the economy was indeed a most important condition in the pathogenesis of infectious diseases, in that it gave occasion to the development of the specific micro-organisms; but how was it possible to explain, other than by the intervention of these, the diversity of form of infectious and contagious maladies? Certain forms of bacteria were found constantly associated with the distinguishing phenomena of certain diseases, and there must be some reason for this. It had never been shown that microbes were formed *de novo* within the organism, and M. Peter had failed to account for their presence in disease.

It is unnecessary to reproduce the arguments of those who contended for the doctrine of infection through the agency of micro-organisms, for they are familiar to all. Thus far in the discussion the bacteriologists seem to have had the best of the argument, but many of the facts brought forward by M. Gautier are new, and there has not yet been time to digest them and to study them in all their bearings. M. Peter's followers are like a newly-equipped army fighting with strange weapons, with the use of which they are not yet familiar, and we cannot judge from the first battle what they may be able to accomplish when they have learned how to handle effectively their new arms. And though the best generals are now on the side of the bacteria, it does not follow that the leucomaines will not be able to make a good fight for recognition.

A CRITICISM OF THE NEW YORK ACADEMY OF MEDICINE.

THE New York correspondent of the *Journal of the American Medical Association* sends to that journal a criticism upon the New York Academy of Medicine which will, we think, be looked upon as unwise and unnecessary, if not actually malicious. The writer refers to the various changes which have been made in its organization, and admits that many of these are improvements. In fact, the only point which he criticises is the alleged removal of all ethical elements from the Constitution and By-laws.

"Practically," he says, "the only reference to the matter of discipline now found is in the eighth article of the Constitution, in which it is provided that the Academy may, by a three-fourths vote of the resident Fellows (the printed call for the meeting having contained a notice of the motion to suspend or expel), suspend or expel a Fellow 'for violation of its regulations.' The only other reference to discipline in the Constitution is in Article VII., where it is stated that the certificate of fellowship may be revoked for cause; but as there is no provision whatever for the manner in which this revocation is to be accomplished, it really amounts to nothing. The only reference of the kind in the By-laws is in the eleventh sec-

tion of No. X., which reads as follows: 'It (the Council) shall, on a written statement signed by a complainant, and duly forwarded through the Recording Secretary, take cognizance of any complaint against a Fellow. The Council may, after investigation, dismiss a complaint or transmit its finding thereon to the Academy for further action.' From this it will be seen that the matter of disciplining is therefore wholly comprised in Article VIII. of the Constitution, which, as just mentioned, prescribes that he may be suspended or expelled for violation of the Academy's regulations. As there is nothing whatever in these 'regulations' of the faintest ethical import, it is evident that a Fellow can be suspended or expelled solely for a breach of certain routine rules. He may be a debauchee or sot, a blackleg or a thief, but so long as he acts in accordance with these 'regulations,' the Academy cannot touch him; and if it attempted to do so, the defence that he had not violated the regulations would hold good in any court of law. There is not even the saving clause of 'conduct unbecoming a gentleman' anywhere to be found.

"Furthermore, it is not necessary, so far as any statutory provisions are concerned, that in order to belong to the Academy a person should be a *regular* graduate in medicine. So far as regards any restriction in the Constitution or By-laws, a homœopath, eclectic, 'physio-medical,' 'herb doctor,' or any kind of a charlatan whatever is entitled to become a Fellow if only he is the possessor of a diploma or license, and has resided in New York or its vicinity for three years. There is absolutely nothing said about what sort of a college or other body the candidate must have derived his diploma or license from; it is simply required that he "must have been a graduate or licentiate in medicine." It is noticeable that the committee on education, as well as that on ethics, has been entirely abolished."

The conclusion to which the writer points is that the Academy is now not in a position to have representation in the American Medical Association.

It will seem to all fair-minded persons that it would be time enough to attack the Academy when some actual offence had been committed. No one in the city doubts that care will be taken as to the character of its membership. The object of the Society has always been that of a scientific body, and its present organization is intended to promote that object.

After a year of unexampled prosperity and useful work, some one must, forsooth, cry out that the Academy has no Code! Well! neither has the French Academy. It does not live among barbarians, and its membership is of such a character that it does not need to incorporate the Ten Commandments into its By-laws in order to keep out rascals. Doubtless there are societies which do require such written safeguards, but the New York Academy, we presume, believes that they are not necessary for the prosecution of its work.

THE LAST VANDERBILT GIFT.

THE College of Physicians and Surgeons of this city has now received half a million dollars for a college building and its endowment, a quarter of a million for a Maternity Hospital, and a quarter of a million for a Dispensary. Including considerable already owned by its faculty, the institution is now by far the richest medical college in the country. As its management is in the hands of wise and conservative men, there can be no doubt but that it will before long do educational work, which will very greatly redound to the credit of our city and country.

We trust that it will soon remove the reproach which now falls upon this city, of having no medical college, except the Woman's, which compels a three years' graded course.

ANOTHER OBJECTION FROM ABROAD TO THE WASHINGTON MEETING.

DR. L. H. PETIT, writing in the feuilleton of *L'Union Médicale*, asks what is to become, now that there has been a reorganization of the American Committee of the International Congress, of the magnificent promises made in Copenhagen by Dr. Billings. He says that when the proposition to hold the Congress in Washington was made, M. Verneuil observed that the expense of the voyage would be a considerable tax upon the resources of many European physicians, who would like to attend the meeting if held nearer home; that those who could afford to go were advanced in life and could not stand the fatigue of the voyage; while those who were able to endure the fatigue were young and could not afford the five or six weeks out of their time, and three or four thousand francs out of their purses, required for a trip to Washington. To which Dr. Billings replied that the United States would feel so honored at being the place of meeting of the Congress that he was sure that they would take upon themselves the expense of the voyage and of the sojourn in Washington of the European physicians who might wish to attend the Congress. It was this promise, M. Petit says, which decided the vote of the assembly. Well it might!

We fear, however, were such a promise made and fulfilled, that the District of Columbia would be too confined a space in which to receive and care for the recipients of our oriental hospitality. But the United States is not in that sort of business just now, we imagine. And it is to be feared that our visitors will be obliged to content themselves with the remission of the $10 admission fee, which is promised them, we believe; although the writer from whom we have quoted thinks that that would hardly be a sufficiently tempting bait to allure physicians across the Atlantic, however great may be their love for international medical science.

How large this world of ours is; and how small men sometimes appear in comparison with it!

A COLD IN THE HEAD.

DR. DAVID LEE recently read before the Harveian Society, of which J. Hughlings Jackson is president, a paper on the "Neurotic Treatment of Catarrh." He considers the diaphoretic treatment of catarrh as entirely opposed to the pathological condition, which is a neurosis in which the vaso-motor system is very largely concerned. An impression of cold from draughts, insufficient clothing, or wet clothing, makes an impression on the surface of the body or the cutaneous-nerves which is by them transmitted to the nerve-centres. The effect is not immediately manifested, but after a few hours a chilliness of the surface is experienced, clearly due to a

general vaso-motor spasm of the cutaneous vessels, and accompanied by flying pains and aches in the limbs which are probably really central and not peripheral, and due to disturbed vascular conditions of the nerve-centres themselves. The doctor, after describing the territories which the vaso-motor spasm thus invades, goes on to outline his treatment, the indications being to soothe the reflex disturbance of the central nervous system, to quiet the local congestion and hyperæsthesia of the nasal mucous membrane, and to arrest the flux if it has already commenced. To completely win the confidence of the learned body before whom he read his paper, he tells what he does for himself when he has a cold. He takes forty to sixty grains of bromide of potassium, repeating the dose in six hours, and if necessary repeating it again after the same interval has elapsed. He paints the nasal mucous membrane, especially of the inferior turbinated bones, with four per cent. solution of hydrochlorate of cocaine by means of a camel's-hair brush; and for the flux he uses fifteen minims of the tincture of belladonna in a little water every hour or two, until his throat feels somewhat dry. He says: "Since I have hit upon this plan I have never failed rapidly to arrest my own catarrhs, nor have I failed in any instance in which I have myself been able to superintend the administration of the remedies."

In the discussion which followed the reading of this paper the learned members defended diaphoretics, one because experience had proved that they had been of use; another made a plea for the time-honored theory of a chilled exterior and an overheated interior of the body; while still another thought "diaphoretic treatment most in accord with the natural process of cure."

The contagiousness of colds was also discussed, but, unfortunately, our English brothers did not throw any light on this question, which is evidently often asked to vex the practitioner on the other side of the Atlantic as well as this.

THE HISTORIES OF THE ROYAL COLLEGES OF PHYSICIANS AND SURGEONS.

The occasion of laying the foundation-stone of the new hall for the joint examination of students in medicine and surgery, by the Queen of England, has called to mind the many strange circumstances connected with the history of the Royal Colleges of Physicians and Surgeons. Until the year 1422 there was no restraint in the practice of medicine in England, when "the persons, male and female, who practised physic" were called upon to pass an examination before one of the universities. In 1513 the next step was taken, by giving the bishops and their vicar-generals the power to license practitioners. This plan continued for five years, when Linacre persuaded Henry VIII. to found the College of Physicians. Slow progress was made from this time, and their home was destroyed in the great fire of London; they struggled on, however, until the time of Harvey, who gave a series of lectures describing his then novel views as to the circulation of the blood and action of the heart. Still they lost ground and could not pay their rent, and their building was about to be confiscated and sold by auction, when Dr. Baldwin Harney purchased it and gave it to the College in perpetuity. Matters afterward took a turn for the better, and after changing to a new building in Warwick Lane, eventually moved to their present home in Pall Mall East.

The policy of those who have from time to time controlled this college has been often condemned. Even during the eighteenth century they maintained their high and dry isolation from general practitioners, and insisted on graduation at Oxford or Cambridge as a preliminary to membership. As one of their own presidents once wrote, they were "wrapped up in the contemplation of their own dignity." Evidently too much ignorance, pedantry, and conceit were sheltered by the ægis of their protection.

The College of Surgeons was not incorporated until the year 1800, so that it is quite a modern institution, so to speak. The history of the English surgeons, however, can be traced back to mediæval times, when they had as associates the barbers; for in those days the barber was called upon "to shave, to perform cold affusions, to bleed, and perform operations." They formed part of the London city corporations under a charter granted by Edward the Second. The two branches of the profession did not agree and they parted company, but in 1540 again united, on the understanding that, with the exception of teeth-drawing, no barber should perform any operation. This union lasted two centuries, until 1745, when they finally separated for ever; but the barbers seemed to have had the best of the bargain, for they retained the building, nearly all the property, and even the anatomical preparations and drawings.

The surgeons from this time increased in number, but were bitterly opposed by the physicians, who would not allow them to prescribe any internal remedy, even when in a surgical case it was necessary. As Chevalier remarked, "if a man had but a boil, he must have a surgeon to apply a plaster, a physician to order a purge, and lastly, an apothecary to put it up." Early in the last century there were but two hospitals in London—one received no pupils, and the other but nine at a time; while the barbers, having a monopoly of dissection, enforced rigorously the prohibition of dissection outside their hall.

Happily, all this is now reversed, the city charter was abandoned, and in 1800 they were constituted the "Royal College of Surgeons." With the traditions of Hunter, the great surgeon, and the possession of his museum of priceless value, they have made rapid strides, and with the liberal steps taken in 1844, have to this day increased yearly in importance and public estimation.

The co-operation between the two representative English medical colleges, after so many years of strife and jealousy, will doubtless be productive of much good, and the joint examinations will remove many difficulties from the path of the medical student.

A Bill for an Act to Regulate the Practice of Medicine and Surgery in the State of Iowa has recently passed the Legislature of that State and become a law, though its penalties are not to be enforced until January, 1887. The law is similar in many of its features to the well-known Illinois law for regulating the practice of medicine and surgery.

News of the Week.

Compulsory Vaccination has been established in Japan, since January 1, 1886.

Extraordinary Prevalence of Aneurism among Foreign Residents in Chinese and Japanese Ports.—At a meeting of the Sei-I-Kwai, Dr. Eldridge, in reporting a case of aneurism, said: "That for some reason, as yet unexplained, residents of European blood in the Chinese and Japanese ports are perhaps more subject to this disease than are any other people on earth. In Yokohama, during seven years, aneurism ranked fourth among the causes of death, every case included in the return being undoubted, and nearly all submitted to post-mortem examination."

The Journal of Nervous and Mental Diseases has appeared in the form of a monthly, under the able direction of Dr. B. Sachs.

The Appointment of Dr. E. G. Janeway, as successor to Dr. Flint, in the Chair of Medicine at Bellevue Medical College, is a most fitting one, and cannot fail to be generally approved.

Another State Board of Health.—The bill to create a State Board of Health in Ohio, having already passed the Senate, was passed by the House on April 17th, by a vote of 78 to 12.

Dr. Fancourt Barnes published, some time ago, a German Medical Dictionary, which Dr. George R. Cutter, of this city, claims was stolen from a dictionary of the same kind published by him a year or two before. We learn from the *Journal of the American Medical Association* that the charge is an unjust one, for one reason because Dr. Barnes' work contains 22,000 words, Dr. Cutter's only 13,000. The charge against Dr. Barnes is a serious one, and we should be glad to see his name cleared.

The Chicago Medical Society.—We are glad to learn from the report of its Secretary, Dr. Montgomery, that this Society is in a state of greater prosperity than ever before. It now has a membership of 325, and during the past year held twenty-four meetings.

A Knighthood Declined.—We never before have had the pleasure of recording the refusal of knighthood by an English doctor. Mr. Savory, President of the Royal College of Surgeons, has done this.

Heroism and Rabies.—We are informed of a courageous act on the part of a medical student named Harris, attached to Charing Cross Hospital, who one day last week seized a mad dog which had attacked a lady at the Charing Cross Restaurant. The animal, notwithstanding it was muzzled, managed to bite Mr. Harris in the hand, who did not, however, relinquish his hold, and called a policeman to his aid, who refused assistance until Harris said, "If you do not help me I shall let the dog loose on you." He then managed to twist the chain round the dog's neck, producing insensibility, during which it was taken to the station by four constables. The hero of this exploit left London for Paris on Thursday, accompanied by four fellow-students, to submit to the treatment of M. Pasteur. The dog died two days after its seizure, from rabies.

Extraordinary Subject for a Prize Essay.—The Paris Academy of Medicine has chosen an extraordinary, not to say an impossible, subject for a prize essay this year—"Préciser par une Série d'Observations s'il existe un Traitement Abortif de la Syphilis Confirmée" (to determine by a series of observations if there exists an abortive treatment of confirmed syphilis), upon which M. Diday has suggested that the Academy must have been seized with an economical fit, and that it would be interesting to see if any one could manage to write a paper of four hundred pages on abortive treatment directed against confirmed syphilis.—*The Lancet.*

College Commencements in St. Louis.—The St. Louis College of Physicians and Surgeons has graduated a class of 17, the Missouri Medical College a class of 86, the St. Louis Medical College a class of 18.

The Fifty-second Annual Commencement Exercises of the Medical Department of the Tulane University of Louisiana were held on March 31st. A class of 63 was graduated.

The Columbus Medical College graduated a class of 19 at its Annual Commencement on March 5th.

On Account of the Cyclone which recently devastated Helena, the Arkansas State Medical Society will meet (April 28th) at Little Rock.

International Congress of Hydrology and Climatology.—The next International Congress of Hydrology and Climatology will be held at Biarritz, France, October 1, 1886, instead of Beyreuth, Bavaria, as previously stated.

Medical Association of the District of Columbia.—At a stated meeting of the Medical Association of the District of Columbia, held on the 6th inst., the following were elected officers for the ensuing year: Dr. J. M. Toner, President; Dr. J. W. Bulkley, First Vice-President; Dr. George Byrd Harrison, Second Vice-President; Dr. Lachlan Tyler, Secretary; Dr. S. S. Adams, Treasurer.

Dr. Ed. C. Harwood has been appointed Visiting Physician to the Hospital for Nervous Diseases on Blackwell's Island, to fill the vacancy caused by the death of Dr. Delany.

Sensible Words from the South.—The *New Orleans Medical and Surgical Journal*, the leading journal of a large Southern section of our country, says editorially, with regard to the next meeting of the American Medical Association: "We sincerely hope that the sturdy and conservative members may finally come to an amicable agreement over the policy and plan of organization which best accord with the purposes of the international body. Our foreign brethren demand the local organization of the Congress upon a broad and liberal basis. They demand that the various sub-committees and sections shall be composed of the representatives of American medicine, men of international prominence, regardless of their State residence, their Association membership, or their opinions on questions of medical ethics. The wishes of our invited guests are entitled to some respect. Without their co-operation the coming Congress will certainly lose its international character and become simply a local gathering."

STARLING MEDICAL COLLEGE graduated a class of 28 at its Commencement on March 4th.

THE MEDICAL COLLEGE OF VIRGINIA, at its annual commencement, March 10th, graduated a class of seventeen.

THE INTERNATIONAL CONGRESS AND THE APPROACHING MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—The Executive Committee appointed by the "Enlarged Committee" of the Association has been actively at work for several months. Just what it has succeeded in accomplishing no one seems to know. The organ of the Association, and those journals which echo its oracular utterances, assure us weekly of the high degree of success which it is attaining, but give us no particulars. Their assurances, however, strongly resemble those which a late Ohio politician was accustomed to give to the faithful: he would "claim it, and claim it exultingly," until the official returns rendered further deception impossible. But there are many evidences that all is not well with the Executive Committee. They can find plenty of men who will gladly accept the offices, but the men who would honor the offices are slow to accept them. The death of Dr. Flint and the paralysis of Dr. Davis have still further weakened their arrogance. They can have a successful Congress, so far as numbers will render it successful; all will admit that; but unless many of those who are now holding aloof can be induced to assist, the Congress cannot be successful, in the best and proper sense of that word.—*Columbus Medical Journal.*

SIR JAMES PAGET, Professor Burdon Sanderson, Dr. Lauder Brunton, and Sir H. Roscoe have consented to serve on the Commission to inquire into M. Pasteur's method of inoculation for hydrophobia.

A LOW TEMPERATURE.—Dr. G. F. Harvey, of Parsons, Kan., reports in the *Kansas City Medical Index* a case of a young woman who had suffered since childhood from cardiac asthma and emphysema. A few days before death, while suffering from general anasarca, she had a temperature under the tongue of 92° F.; two days later it was 94° F. She died three days subsequently.

THE ACADEMY OF MEDICINE OF ROME has voted to send a delegate to Paris to learn Pasteur's method of prophylactic inoculation against rabies. It is rumored that the German Government will send a commission, composed of Drs. Virchow and Koch, to study Pasteur's methods. M. Pasteur is being loaded with honors, as he has been decorated by nearly all the sovereigns of Europe, for his remarkable discovery of the means of prevention of hydrophobia, and the King of Portugal has just sent him an autograph letter, conferring on him the Grand Cordon of the Order of St. Jacques, a decoration specially designed to recompense scientific merit. This letter was handed to M. Pasteur by Dr. Bournay, one of the doctors who arrived in Paris on the 2d inst. with three children from Portugal, reported to have been bitten by a mad dog. The children are sent at the expense of the Queen, to undergo M. Pasteur's treatment.

A MILLION DOLLARS TO A MEDICAL COLLEGE.—The daily papers of April 17th announced the following: Messrs. Cornelius Vanderbilt, William K. Vanderbilt, Frederick W. Vanderbilt, and George W. Vanderbilt have each contributed $62,500, or a total of $250,000, for the erection and endowment of a new building to be supplementary to the two already endowed, and to be known as the Vanderbilt Clinic of the College of Physicians and Surgeons.

This will be a building devoted entirely to the clinical instruction of students, except the lower floor, which will be a free dispensary. Of the $250,000 donated by the young Messrs. Vanderbilt, $150,000 will be used in the construction of the building, and the balance will be used as the endowment for the running expenses of the clinical school and the free dispensary. The new building will be erected at the corner of Tenth Avenue and Sixtieth Street, adjoining the Sloane Maternity Hospital, and, like it, will be 75 by 100 feet. The Vanderbilt Clinic will be under the control of a board of five managers, in which Frederick W. Vanderbilt will represent the donors, Dr. John C. Dalton, the president of the college, will represent the institution; Dr. William H. Draper, the Board of Trustees of the college, and Drs. Henry B. Sands and James W. McLane the Faculty. To these gentlemen will be entrusted the erection of the building, the investment of the surplus funds, and the equipment and furnishing of the institution. The plan proposed includes the free medical dispensary on the first floor, an amphitheatre for clinical purposes on the floor above, and a number of small rooms for private instruction or instruction in specialties. The Vanderbilt Clinic will not be in the nature of a hospital, as the only cases to be treated here, in the presence of classes, will be those of patients who are able to move about, and who are not confined to beds. The clinical work will be on diseases of the eye, ear, throat, heart, lungs, nerves, and genito-urinary organs, skin diseases, and diseases of women and children. In the great amphitheatre-shaped room all lectures on medicine and diagnoses of diseases which fall under a physician's rather than a surgeon's care will be delivered.

THE LOUISIANA STATE MEDICAL SOCIETY held its annual meeting at New Iberia, on April 14th.

THE CORNER-STONE OF THE NEW BUILDING of the College of Physicians and Surgeons, at the corner of Tenth Avenue and Sixtieth Street, is to be laid to-day. Mr. Chauncey M. Depew delivers the oration.

PROFESSOR PASTEUR PROSECUTED.—Pasteur has been prosecuted for practising medicine and surgery without being legally qualified. The case, however, fell through, his defence being that he employed a duly qualified medical man to perform his operations.

A RIVAL TO PASTEUR.—Hoang-nan appears to prevent hydrophobia when given systematically in full doses, *i.e.*, one to two grammes daily of the powder. So says Dujardin-Beaumetz, who has given it to twenty-four persons who had been bitten by rabid dogs.

THE INNOMINATE ARTERY WAS RECENTLY LIGATURED by Mr. Bennett May, of London. The patient, who so far has done well, was a laborer suffering from a large subclavian aneurism. Dr. V. Mott first performed this operation, his patient living four weeks. Dr. Smyth, of New Orleans, is, we believe, the only surgeon who has successfully tied this artery.

Removal of a Tumor of the Brain.—Dr. J. O. Hirschfelder, of San Francisco, reports a case of brain tumor in which the disease was diagnosticated, its locality mapped out, and an operation performed. The bone was removed, and the tumor found as expected. It was a gliomatous mass, however, and infiltrated so that only a part could be removed. The patient died eight days later. The symptoms pointed to a tumor of the middle part of the right post-central convolution, and it was found in that locality.

The French Association for the Advancement of Science will hold its fifteenth meeting at Nancy, August 12th next, under the presidency of Professor Friedel.

An Unhealthy Country.—Among the 8,259 districts into which Italy is divided, there are 1,876 in which there are no water-closets, or no substitutes for them, except mother earth. In 2,836 districts the dwellings are small and unhealthy. In 1,483 districts the houses have no chimneys. In 4,965 districts meat is not eaten, and 3,637 have no slaughter-houses. Among 10,000 Italians, only 23 are meat-eaters. In 1,437 districts there are no regular physicians. In 1881 there were 104,067 cases of pellagra. From 1835 to 1881 Italy was visited by the cholera seventeen times.

Cholera has reappeared in Italy near Padua; also in France. Several cases suspected to be cholera have appeared in Spain.

Medical Reform Abroad.—Complaints of overcrowding of the profession and of abuse of medical charities are being made in Belgium, Berlin, and Vienna. In the latter city it is stated that there is one physician to every 500 inhabitants. As one-half the inhabitants get medical services at the hospitals, it leaves practically only one doctor to every 250 inhabitants. The free dispensaries are especially charged with injuring the practice of the physicians.

Peach-root Tea is an Efficient Remedy for epilepsy, according to Dr. J. L. Dorset, of Dorset, Va. (*Medical Age*). Three or four ounces of an infusion are to be given daily. Dr. Dorset reports one case in confirmation of his view.

Lanolin, the new basis for ointments, has been used in this city to a considerable extent, and so far it has caused considerable disappointment.

The Microbe of Dengue.—A Texas physician, Dr. McLaughlin, claims to have discovered and cultivated the microbe of dengue. It is found uniformly in the blood of patients suffering from this disease.

The Archduke Charles Theodore of Bavaria, who practises medicine, has obtained permission from M. Pasteur to be present at the inoculations in the laboratory of Rue d'Ulm. The Archduchess, who helps her husband in his professional labors, will accompany him as an assistant.

Sir Andrew Clark paid a professional visit to a lady in the south of France, being absent from London five days. For this he received a fee of $7,500. The lady also gave him a sum of $25,000 for distribution among the London medical charities. The London Hospital and Medical College got $15,000 of this.

For Diabetes Insipidus give valerian, according to Demange. Trousseau and Bouchard also have recommended this drug. Ergot is also much used.

Alveloz in Cancer is a disappointing drug, yet worth a trial, according to late experiments by French physicians.

The Curette and a Caustic are the best things for lupus, according to Unna. The fashionable caustics are pyrogalic acid and ichthyol.

Ichthyol, of which there is now much talk, is described chemically as sulpho-ichthyol-ammonium. The best results from it, says Unna, are obtained by a local application in acne and acne rosacea. It is also useful given internally (gr. xv. daily) in pityriasis, seborrhœa, sicca, and ichthyosis. It is unfortunate that the manufacture of ichthyol is in the hands of a company which has certain patents or proprietary rights over it.

Professor Strümpell, of Leipsic, has received a call to Erlangen. He is to be succeeded by Professor F. A. Hoffmann, of Dorpat.

The Late Austin Flint, M.D., LL.D.—At a regular meeting of the New York County Medical Association, held at the Carnegie Laboratory, April 19, 1885, the following was unanimously adopted:

Whereas, It has pleased God, in the exercise of his Divine Will, to remove from the sphere of his usefulness our esteemed co-worker, Austin Flint, M.D., LL.D., revered abroad but best loved at home; and whereas it is but proper that we take to ourselves that consolation which comes from the rehearsal of his many virtues. Therefore be it

Resolved, That as an Association, to whom he gave his latest work, and ever his cherished counsel, we add our own to the many other testimonies of his worth.

Resolved, That we recognize in him an author of marvellous industry, who has made his impress on the medical thought of the age; modest and just, but still a master of deliberate statement; conscientious in the recognition of the labors of others, and despising not the humblest contributor to that science to which he devoted his life; a practitioner of his art without device; zealous for the dignity of his calling; suave, considerate, and gentle; one who worthily gained the gratitude of his patients, and will ever live in their most blessed memories; a consultant who dispensed rich stores of knowledge, ever judging kindly, more careful of the rights of others than his own, cheery and abounding in charity for his brethren; a teacher, hand-in-hand with his pupil, analytical, painstaking, less eager for glory than exactness, ever approachable, and always ready with a reason for the faith that was in him, and a man in all the walks of life blameless, "who hath borne his faculties so meek," and "hath been so clear in his great office," and who, laboring to the last, hath fallen in sight of the promised land of his cherished hopes. And be it also

Resolved, That we tender to those of his own household and kinship our heartfelt sympathies, knowing full well that to his son his life was a pæan of touching affection, and to his widow one long benediction.

John Shrady, M.D.,
E. S. F. Arnold, M.D.
J. W. S. Gouley, M.D.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 15, 1886.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT introduced DR. A. VANDER VEER, of Albany, N. Y., ex-President of the Medical Society of the State of New York.

THE CORRESPONDING SECRETARY acknowledged the receipt of a communication from the Corresponding Secretary of the Nebraska State Medical Society, accompanied by a volume of the Society's transactions.

DR. A. B. JUDSON reported from the Section in Surgery.

DR. H. F. CHAMBERLAIN reported from the Section in Public Hygiene, and asked the Academy to adopt resolutions adopted by the Section, condemning the Cullen Bill already passed by the State Senate, and providing for establishing a manure-dump in the city of New York.

The resolutions went over under the rules, and when brought up subsequently, Dr. Roosa announced that their adoption had been rendered unnecessary by the defeat of the bill in the Assembly.

DR. J. C. PETERS said it was worthy of special note that the defeat of the Cullen bill was due largely, if not entirely, to the vigorous opposition made to it by the committe sent to Albany from the Section in Public Hygiene. The first work of the Section had thus been crowned with success.

DR. H. GRISWOLD reported from the Section in Obstetrics.

DR. STEPHEN SMITH then read a memoir of

ALFRED CHARLES POST, M.D., LL.D.,

which was a calm and dignified exposition of the spotless life and character of our Nestor in Surgery.

DR. A. VANDER VEER, of Albany, N. Y., read a memoir of

S. OAKLEY VANDER POEL, M.D., LL.D.,

which was a chaste, sympathetic, and lifelike delineation of the work and worth of one who had been an ornament to his profession, and whom his profession had been delighted to honor.

THE PRESIDENT, DR. A. JACOBI, read a memoir (see p. 464) of

AUSTIN FLINT, M.D., LL.D.,

in which he paid a glowing and most worthy tribute to the purity, the scholarly acquirements, the eminence, and the great knowledge of his highly distinguished predecessor.

DR. T. HERRING BURCHARD then read a paper (see p. 461) on

PELVIC ABSCESS IN THE MALE,

after which the Academy adjourned.

PROFESSOR R. T. EDES should be credited with the lecture on the subject of "Success in the Medical Profession," referred to in THE RECORD of March 6th. Our account was based upon an Associated Press despatch, which got mixed (as usual). Dr Edes is Jackson Professor, not Professor Jackson.

THE FIRST USERS OF NUTRIENT SUPPOSITORIES.—Mr. Thomas Latham, of this city, writes: "The *British Medical Journal*, Mr. Godlee, and Dr. Barlow are mistaken in supposing the application of nutrient suppositories to rectal feeding to be a new idea. Upward of ten years ago, while with Mr. Sands, of Vanderbilt Avenue, I prepared such suppositories, using Valentine's extract of beef and sufficient gelatine to solidify the extract, care being taken that the mass was soft enough to be readily absorbed."

Correspondence.

OUR PARIS LETTER.

[illegible]

THE INFLUENCE OF THE STUDY OF HYGIENE ON THE DURATION OF LIFE—EPIDEMIC OF TYPHOID FEVER—ANTISEPTIC METHODS—SCURVY—THE LATE ACADEMICIAN FAUVEL.

DR. PROUST, the successor to Professor Bouchardat in the Chair of Hygiene at the Faculty of Medicine of Paris, delivered his inaugural lecture on Saturday last, March 27th, when the amphitheatre was quite crowded, and many of the professors of the faculty also attended to welcome their new colleague. Dr. Proust began his lecture by a graceful tribute to his predecessor Professor Bouchardat, after which he confined himself to the advantages of a proper study and strict application of the principles of hygiene. Before the revolution, the mean duration of life in France was twenty-nine years; it is now from thirty-seven to forty years, and in women it has even been raised to forty-two years. But it is, particularly as regards the mortality in early childhood that this difference is more striking. Before the application of "the law of Roussel," which regulates the duties of nurses toward their nurslings, the mortality used to be thirty per cent. in the Calvados (one of the centres of baby-farming); it is now no more than five or six per cent., it used to be eighty per cent. in the department of the Seine, whereas now it is scarcely twenty per cent. It is also to the progress of hygiene that is due the disappearance of purulent infection from the hospitals, the improved method in dressing wounds contributing in a great measure to the same end. The beneficial results obtained by a more rigorous attention to the principles of hygiene have been in obstetrics still more remarkable. It is not so very long ago when, at the old Hôtel Dieu, a woman awaiting her confinement had to lie in the same bed with a corpse or with a patient suffering from puerperal fever. Even in those times this state of things was strongly condemned, and women of the most sensible class of the community used to go out to the country to be confined. The Constituant then caused the Maternity to be built. In the new hospital, although each patient had her own bed, the mortality was ten per cent., that is to say seventeen times greater than that among women confined in the neighborhood outside the hospital. Professor Tarnier, who is the principal accoucheur of the Maternity, has effected great improvements, which has brought the mortality down to three per cent., and since the strict application of the antiseptic methods during the last few years, it is no more than one per cent. Scurvy, which used to decimate the sailors and those proceeding on long voyages, is now scarcely ever heard of. The disease is due principally to the want of vegetable food, but the administration of lime-juice contributes in a great measure to ward off the disease. During the last thirty years great strides have been made, by means of International Congresses, to prevent the incursion of infectious diseases, and it must be said with some success, a result mainly brought about through the instrumentality of the late Dr. Fauvel, the eminent Academician and hygienist.

At a recent meeting of the Société Médicale des Hôpitaux, Dr. Debove read a note to illustrate the contagious nature of typhoid fever. He was called in to attend five children of the same family suffering from typhoid fever. Another family of six children came from the provinces to live in Paris, which place they reached on November 15, 1885. One of the children was ailing before he left the country. On the 20th he presented all the symptoms of typhoid fever. Another brother was seized with the disease on November 23d and died on January 24th following. A third fell ill on November 29th,

a fourth on December 17th, a fifth on December 29th. The sixth escaped. The children affected with typhoid fever were separated from the others; hygienic precautions were observed, and the linen was disinfected, as well as the dejections, cesspools, and water-closets. From the above cases Dr. Debove concludes that typhoid fever can be contracted by direct contact and added that in Germany it is believed that the germs of typhoid fever are expelled by the dejecta, and, after undergoing certain modifications, are capable of communicating the disease to healthy organisms.

It is usually easy to distinguish the soft chancre from the syphilitic chancre, but as Dr. Balzer observed at a recent meeting of the Société de Biologie, the diagnosis is sometimes surrounded with great difficulty. In this case inoculation is frequently resorted to, but this operation is not always free from danger. Dr. Balzer therefore proposes another procedure, which is applicable to all cases. It consists in examining histologically the products secreted by the suspected ulcerations. If one has to do with a simple herpetic ulceration, it will be found that the secretion contains pus-globules and epithelial cells, the same is the case with a syphilitic lesion. When, on the contrary, it is a soft chancre the latter is found to contain elastic fibres in more or less great number, mixed with the pus-globules and epithelial cells. The explanation of this difference proposed by the author is that herpes and the hard chancre, are ulcerations purely epithelial, whereas the soft chancre is a lesion exclusively dermic. Dr. Balzer had recourse to this means of diagnosis fourteen times, and he was always successful.

Dr. Edward Fournié, the editor of the *Revue Médicale*, died on March 24th after a long and painful illness. He was a distinguished laryngologist and aurist, and was for a long time director of the National Asylum for the Deaf and Dumb. He was fifty-three years of age.

I have also to report the death of Dr. Gillette, which has just taken place at his residence in Paris. He took his degree in 1867, and was a distinguished hospital surgeon.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ROYAL CEREMONY ON THE EMBANKMENT—THE MEDICINE OF THE PAST—CLERICAL LICENTIATES AND BARBER-SURGEONS—SURGICAL MEDICINE AND MEDICAL SURGERY—HEPATIC PHLEBOTOMY—PARACENTESIS FOR BRONCHIECTASIS—SUPRA-PUBIC LITHOTOMY—THE HYDROPHOBIA SCARE—THE LATE MR. STREATFEILD—THE PARKES MUSEUM AND THE SANITARY INSTITUTE.

LONDON, March 27, 1886.

THE past week has been marked by the occurrence of two noteworthy events in the medical world of London—one social, the other scientific. By the former, I mean the laying of the foundation-stone of the new Examination Hall of the Royal Colleges of Physicians and Surgeons, on Wednesday last, by the Queen in person. By the latter, I mean the discussion at the Royal Medical and Chirurgical Society on the treatment of bronchiectasis by paracentesis.

The royal ceremony, on Wednesday last, merits more than a passing word. The actual participation of the nominal head of the State in the proceedings was in itself noteworthy, and the more so considering the virtual retirement in which the Queen has lived of late years. She was, moreover, not the only member of the royal family present. The pageant was conducted in semi-state, and attracted a large concourse of spectators. "Royal weather" favored the occasion, the bitter weather of a week previous, with bleak east winds, having changed by magic, as if on purpose. The laying the foundation-stone of an examination hall does not in itself appear an affair of much importance, but more is implied in the circumstance than appears on the surface. By the erection of a building for their joint use, the two colleges have taken the first step toward their virtual union, and this step has received the patronage of Her Majesty the Queen, of several members of her family, and of many representatives of the Government present in their official capacities. No one can imagine that when the building is completed its spacious chambers will be devoted solely to examination purposes. It is more probable that a new university may see birth in the building in the Savoy, looking down on the Thames, and the events of the past week render it almost a foregone conclusion that the two colleges will not have much difficulty in obtaining a royal charter empowering them to grant degrees in medicine and surgery.

The ceremony on Wednesday last implied a greater recognition of medicine and surgery by the State than has hitherto been accorded. Many readers may be surprised to learn that five centuries ago there was no such recognition at all. It was only in 1422 that any notice was taken of the profession, and then a State order was made that those who had not a university degree should forthwith be examined at one of the universities, on pain of condemnation by the Privy Council. In 1513 the authority of the Church was recognized to such an extent that the Bishop of London was made supreme in authority over the London practitioners, who had to be examined by him, he being *assisted by four doctors of medicine or surgeons!* The provincial Bishops were similarly entrusted with the licensing of country doctors. The London College of Physicians was founded in 1518, by royal letters-patent, and remained under the control of the Bishop of London for five years. In 1523 it was set free by statute, but the Bishops long retained their licensing power. A relic, in fact, still remains in the power which the Archbishop of Canterbury still has of giving degrees in medicine, and which he occasionally exercises. The distinction in question is termed M.D. Lambeth, the archiepiscopal palace being situated at Lambeth, on the south side of the Thames, not far from St. Thomas' Hospital. The degree is nowadays scarcely ever conferred, except on persons already qualified as medical practitioners, though the opposite was frequently the case in bygone years. The first home of the College of Physicians was near St. Paul's. It occupied more than one building in the city, and only removed to its present site at the West End (Pall Mall) in 1825.

The College of Surgeons is of much more modern date. For many years only barber-surgeons existed. A company of these barber-surgeons was formed in 1308, and incorporated, 1462. Subsequently to the latter date the barbers and surgeons quarrelled and separated. They were reunited in 1540, with the proviso that "no barber shall occupy anything belonging to surgery, drawing of teeth only excepted." Distinct surgeons can therefore scarcely be said to have existed till 1540, and even then they and the barbers belonged to the same company. This nominal union persisted till 1745, when the barbers and surgeons again separated, and this time for good. The barbers managed to retain nearly all the joint property, including even the anatomical preparations. The surgeons remained merely a city company till 1796, when through an illegal election the charter was forfeited. A new charter was obtained in 1800, establishing the present Royal College of Surgeons. They were then housed, as now, in Lincoln's Inn Fields, and had just acquired the Hunterian Museum. The present buildings were built in 1813, re-modelled, in 1836, and enlarged in 1852-53. Parliament voted a sum of twenty-seven thousand pounds toward the erection of a museum to contain Hunter's collection. This collection had been, no doubt to their subsequent chagrin, declined by the College of Physicians.

Great have been the changes since the foundation of the two colleges. What would the old barber-surgeons have thought if, flanked by the medical licentiates of the Bishop of London (who would no doubt have snubbed

them heartily), they could have looked down from an adjoining roof on Wednesday's proceedings? They would doubtless have been amazed, but would perhaps have been reassured when, on proceeding to the present College of Surgeons and inspecting the annual calendar, they found the ancient manners still referred to by a formal recital in the present charter (1800) of the former charters and acts of Parliaments granted to the barber-surgeons.

Leaving the past and reverting to the present, I would now claim for the late discussion on bronchiectasis the attention it deserves. The surgery of the viscera is rapidly advancing, and it really seems as if the surgeons were determined every year to encroach more and more on the domain of the physician. The surgeons, if trodden upon in the past, are determined not to be behind in the present. The physicians, to do them justice, are equally eager to avail themselves of surgical methods where desirable. A physician of this era does not send for a surgeon to perform venesection if it be required, but does it himself, usually, unless a general practitioner is in attendance. Dr. George Harley has lately been startling the medical public by performing what he calls "hepatic phlebotomy," for the relief of chronic indurations of the liver. In one case he withdrew a pint of blood in this manner from the hepatic substance. He is about to publish a work on the subject. What a change from the day when a physician is said to have allowed a patient to die because it was beneath his dignity to bleed him, and there was no surgeon at hand to do it!

To return. The discussion referred to was based on a paper prepared jointly by Dr. Theodore Williams and Mr. Rickman Godlee. They described two cases of bronchiectasis which had been successfully treated by them by means of paracentesis. The first was that of a gentleman sixty-seven years of age, who had suffered for two years from chronic bronchitis and emphysema. The expectoration was profuse and fetid. Dr. Williams diagnosed the existence of a bronchiectasis. At his request, Mr. Godlee (having first tapped it with an aspirating trocar and cannula) opened the cavity with antiseptic precautions, and inserted a drainage-tube. The cough nearly ceased, the expectoration became reduced from a pint to a few pellets daily, and also lost its fetor. The patient gained flesh rapidly. The discharge ceased at the end of six weeks, the channel closed, and the wound healed up. Examination of the chest revealed complete disappearance of tubular breathing and shrinking of the chest-wall. Nine months after the operation, the patient remained free from cough or expectoration, and was able to walk four miles.

In the second case, the success attained was not so marked, although considerable relief was afforded. The patient was a girl, aged twenty-one, who, following an attack of typhoid fever, suffered from cough and copious fetid expectoration. Hæmoptysis occurred on three separate occasions—on one of these to the extent of a pint. In this case also paracentesis was performed, though some difficulty was encountered, and an inch of the eighth rib had to be excised before the bronchiectatic cavity could be reached. The wound gradually healed, and when the patient left the hospital there was only slight cough, the expectoration had diminished to about three ounces a day and was only occasionally fetid. The authors considered that the partial success was attributable to the presence of other bronchial dilatations which could not be reached. In four other cases treated by them, complete success was, in their opinion, similarly precluded.

The authors considered that paracenteses of bronchiectases were indicated under the following circumstances:

1. To prevent death from septic pneumonia, where antiseptic treatment had failed to correct the fetor of the sputum and allay the cough.

2. Where the bronchiectases appeared to be confined to one lung, were in the lower lobe, and an adherent pleura overlay them.

Experience had shown the invulnerability of the lung tissue. The operation was not without difficulties, of which the chief was the difficulty of diagnosing exactly the position of the bronchiectasis. This was due to (1) the presence of emphysema; (2) the reverberatory character of the auscultatory sounds in the bronchiectasis.

These difficulties in diagnosis were emphasized by several speakers in the subsequent discussion, the difficulty being considered especially great when total obstruction of a bronchus had occurred. Several of the speakers expressed the opinion that operative treatment should be confined to cases associated with fibrosis and adherent pleura, but Dr. Williams and Mr. Godlee expressed their unwillingness to concur with this view. There was some discussion as to the danger of hemorrhage. It was admitted by most that this danger was but slight, though hemorrhage might occur, and the possibility of this should not be overlooked. Mr. Godlee acknowledged the possible danger of hemorrhage. When the patient's mouth became full of blood, he thought a bronchial vessel must have been wounded, and, under deep anæsthesia, this might cause suffocation. Sir Andrew Clark suggested that hemorrhage might be prevented by sclerosis of the arteries diminishing their calibre. Fibrosis was generally present, he remarked, and in fibroid tissue the arteries participated in the sclerosis.

The Royal Medical and Chirurgical Society held a special meeting on Tuesday last to discuss the subject of supra-pubic lithotomy. The discussion occupied the whole evening, and was participated in by many of the leading authorities on the subject, both metropolitan and provincial.

Mr. Barwell, of Charing Cross Hospital, read a paper on the subject, narrating some cases. In one, a girl of nine, a stone measuring over two inches in its longest diameter was extracted by the supra-pubic operation. The child suffered nothing after the operation, and the wound healed in a fortnight. Mr. Barwell said that the high operation had been too much neglected, and might with advantage be used in other cases than those of very large stones. There was no danger of a permanent urinary fistula, and that of urinary infiltration might be avoided with care. The peritoneum could be raised by injecting the bladder, and as it was barely attached to that viscus, it yielded upward to the slightest touch of the finger. Mr. Barwell maintained that for female children no other form of lithotomy should be practised.

Mr. Rivington, of the London Hospital, read the notes of a case in which he had employed the supra-pubic operation to remove an unusually large stone. The patient had suffered from symptoms of stone for sixteen years, but no stone could be detected on sounding, though on rectal examination a large, round, smooth swelling was detected in the situation of the prostate gland. Median urethrotomy for the purpose of exploration was performed, when it was found that the hard mass was not connected with the prostate, and that the bladder-wall was pressed over to the right by it. A sound pushed far back at length struck a stone. It was grasped by forceps, but could not be moved. Supra-pubic lithotomy was then decided on, and was performed. The stone was found to be contained in a pouch. It could not be moved with forceps, and the lithotrite was found equally useless. The calculus was therefore broken up with a chisel and mallet. The pieces removed weighed collectively twenty-three ounces. The patient recovered from the operation, but cystitis came on some months later, the urine became ammoniacal, and death ensued. At the autopsy, suppurative inflammation of the left kidney was found, with inflammation of the bladder and the pouch in the latter. Mr. Rivington remarked that though

not absolutely the largest stone ever removed from the human bladder during life, it appeared to be the largest removed during life with recovery of the patient from the immediate effects of the operation.

Mr. Jacobson, of Guy's Hospital, read an account of a case in which the high operation had been performed. The patient was a laborer, aged nineteen, who had suffered from bladder irritability all his life, from symptoms of stone for five years, and from cystitis for one year. The sound showed several stones to be present. The supra-pubic operation was selected in consequence of the long duration of the symptoms, and the probability that the kidneys were impaired. The bladder was distended with water (ten ounces), and the rectal bag introduced. The peritoneum was not seen. Only one stone was found at the operation, but two smaller ones escaped through the wound some weeks later, following a rather severe venous hemorrhage. Mr. Jacobson maintained that the operation had a future of revived usefulness before it; and that it would be found of great value by operators who only had to deal with stone occasionally, and who found themselves face to face with good-sized stones in adults. He thought it wise not to attempt to close the bladder with stitches.

A discussion then took place on the papers read. This was opened by Sir Henry Thompson, who prefaced his remarks with a brief tribute to the value of Bigelow's work. The alteration in lithotrity resulting from Bigelow's treatment had, he said, changed the conditions under which lithotrity was now performed, and left a different category for those cases requiring a cutting operation. Stones of two ounces could be removed safely by lithotrity, but an operation was needed to meet cases of stones of over two ounces or two ounces and a half. He agreed with the opinion expressed by both foreign and English surgeons, that the surgeon with little experience or skill had better use a cutting operation, and the best for him was a supra-pubic lithotomy adopting the modern improvements. He considered distention of the rectum valuable, as not only increasing the supra-pubic interval, but as rendering the bladder immobile and raising it out of the pelvis. The views of Bouley and Hildanus were quoted. The latter had shown that in children it was possible to push up the stone above the margin of the pubes by pressure within the rectum. Rectal distention was also valuable in removing large tumors of the bladder by the supra-pubic operation. Sir Henry Thompson concluded his remarks by saying that in supra-pubic lithotomy the wound should not be closed for some days.

Mr. Cadge, of Norwich, thought we should be cautious in our deductions. He was not sure that we ought yet to conclude that the lateral operation might be abolished in favor of the new supra-pubic method, and thought many of the already reported cases might have been dealt with by the former method. He agreed with Mr. Barwell that distention of the rectum was not of much value in raising the prævesical fold of peritoneum, but that it was mainly useful in raising the fundus. Mr. Cadge admitted that an advantage of the high operation was the fact that no stone could be left behind, an occurrence which might happen with the lateral operation. Freedom from hemorrhage had been quoted as another advantage of the high operation, but decided hemorrhage had occurred in three out of twelve cases reported that evening.

Mr. R. W. Parker, of the East London Hospital for Children, had performed the high operation once, and found it easy of performance. He could not go as far as Mr. Barwell in recommending it for female children, and had found urethral dilatation satisfactory in them.

Mr. Bryant, of Guy's Hospital, considered the supra-pubic operation to be probably preferable in dealing with all large stones, especially if there were any kidney disease, though the latter complication would render any operation more dangerous. He concurred with Mr. Parker that in females rapid dilatation of the urethra followed by lithotrity would prove sufficient in most cases.

Mr. Lund, of Manchester, urged that the supra-pubic operation entirely removed the danger arising in the lateral operation from bruising of the tissues. The use of anæsthetics rendered the revival of the supra-pubic operation more easy, as by employing them the pain arising from lifting the floor of the bladder was avoided.

Messrs. Barwell, Rivington, and Jacobson then replied. Mr. Barwell admitted the possible danger of distending the rectum, especially in old people. Mr. Rivington remarked that in females he should mostly prefer vaginal lithotomy, unless the stone were very large. He had, however, removed (by vaginal lithotomy) a stone measuring six inches by five inches, and the wound healed by first intention. Mr. Jacobson recognized the danger of distending the rectum by more than twelve or fourteen ounces of fluid, but expressed his general preference for the supra-pubic operation.

The hydrophobia scare continues, and the "dog order" has been renewed for a further period. According to this, any dog not led or muzzled, or otherwise under control, may be seized by the police, and, if not claimed by his owner, destroyed. The "dog order" may be disagreeable to owners of dogs, but has certainly been beneficial to the public at large, as it has led to a large number of stray dogs—many of them probably diseased in some way, even if not rabid—being seized and destroyed. Thousands of dogs have been killed at the "Dogs' Home," the process employed being to painlessly asphyxiate them in the lethal chamber devised by Dr. B. W. Richardson, F.R.S. Their bodies have been sent into the country, and used as manure. Meanwhile a Hydrophobia Commission is about to be appointed. Although many still exercise a wise scepticism as to Pasteur's results, the opinion is growing that there is something in it, and the appointment of a committee is virtually brought about by the pressure of public opinion.

I lately chronicled the death of Mr. Wordsworth. Another distinguished ophthalmic surgeon—Mr. Streatfeild—has also joined the majority. Like Mr. Wordsworth, he also served as a surgeon in the Crimean War before he commenced his career as an ophthalmologist.

The Parkes Museum and the Sanitary Institute are about to be amalgamated.

ACTINOMYCOSIS IN MAN.

To the Editor of The Medical Record.

Sir: Having read an article entitled "A New Form of Lung Disease" in the March 20th number of The Record, I thought I might profitably contribute on the same subject, more especially because the article has an unimportant error or two. The author of the article made a mistake in attributing to Ponfick the discovery of the germ in the human subject. To Israel, of the Jewish Lazarette, Berlin, belongs that honor, *vide Virch. Arch.*, vols. lxxiv. and lxxviii., *Centralblatt f. Med. Wiss.*, 1883. Ponfick was the first who proved the identity between the actinomycen of men and cattle (Ziegler). But preceding this I have the personal statement of Professor v. Esmarch, that thirty years ago, while he was first assistant to Professor v. Langenbeck, in the microscopical examination of some peculiar-looking pus, from a supposed case of vertebral scrofulosis, he discovered this peculiar- (strahl pilz) looking pilz (germ). He submitted his specimen to his chief, who concurred that it looked like a germ. Professor v. Esmarch made copies of the preparation, which he says he still has in his possession, and was not surprised, when he read the description of Israel, to find that his supposed case of scrofulosis had really been one of actinomycosis. Professor v. Esmarch made this statement before *Ober Staats Arzt*, Albert Köhler, first assistant to Professor Bardeleben, and my-

self (apologies for any breach of courtesies, for I was Dr. Köhler's guest). So this gives Professor Esmarch the credit, and no doubt he deserves it, of being the first discoverer of the germ actinomycen. Professor Esmarch said he had had success in treating the disease by free drainage and free irrigation, and parenchymatous injection of saturated solution of boric acid, frequently used. All observers agree that it is a most malignant germ. The disease, as far as known, occurs in three forms, namely, lung actinomycosis, intestinal actinomycosis, and general actinomycosis. The first form is very well described in the article in THE RECORD. The second form begins primarily in the intestine, and rapidly spreads to the tissues. It has a selective predilection for connective tissues. It generally makes its appearance in the parietal fold of the pelvic fascia, and in the right inguinal region, and may easily be confounded with osteosarcoma of the ileum, if the history of the time of evolution is not carefully taken into account. It is with this form that Esmarch has had the most success with his method of treatment. The third, or general form, was the variety that Israel described. Infection generally goes out from the mouth, by the germs getting under the gums to the alveolar ridge, or infection may take place through a decayed tooth; in fact, the germ has been found in the normal state in the crypts of the tonsils, in the nasal ducts, and in hollow teeth. Bergmann says it is quite the rule to find them in the tonsils of swine, and illustrates the truth of the statement with many specimens. From the mouth the germs progress into the deep cervical fascia, thence down the vertebræ into the mediastinum anterior and posterior, causing mediastinitis, and caries of the bodies of the vertebræ, ribs, and sternum. Infection progresses in nearly all cases by local progression, seldom by metastasis. Of all tissues in the body, it probably has the greatest affection for the connective tissue about the spinal column. The principal diagnostic characteristic of the disease, microscopically speaking, is the presence of innumerable little straw-yellow bags, about the size of a pin-head, which contain the specific germ (Virchow), and on this account making it different in appearance from any other sort of pus. Another diagnostic sign is the severity of its local processes, but with every aid the diagnosis is usually difficult. The disease it is most likely to be confounded with, generally speaking, is *general tuberculosis*.

Respectfully,

A. R. JENKINS, M.D.

HEMPSTEAD, N. Y., March 24, 1886.

[Our correspondent is himself in error in his criticism of our editorial. Israel published two cases shortly after Bollinger's communication, but he regarded it as a peculiar form of septicæmia, and not as identical with the disease described by Bollinger. Esmarch also, although he recognized a peculiar disease, did not understand its nature.—ED.]

THE PATHOLOGICAL FUTURE OF THE NEGRO.[1]

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The negro in towns and cities is in a much better condition as to longevity than in the country, although our census reporter may make a different statement for political purposes. The fact is, in towns and cities negroes are better fed, clothed, and housed, and when sick usually receive very good medical attention; in the country it is the very reverse.

In most Southern States where there is a preponderance of negroes we have what is called stock, or no fence law; the object is to prevent the negro from accumulating, and to make him a hewer of wood and drawer of water as long as he lives. Now, what is the result? It makes him in the country dependent on the landlord, who is dependent on the commission merchant, who often is dependent on the courtesies of the banks for accommodations (financial).

Let one of these negroes get sick, say with any protracted disease—say even pneumonia, which we all know is terribly fatal to the black man. By the time the landlord becomes responsible for, say two or three visits—which he will do if there is a fair prospect for a crop (and if the crop is gathered in the winter months he will not, only in very exceptional cases), he will serve notice to the doctor that he will not be responsible for any further medical attention. What is the end of it generally? A pauper's coffin and a pauper's burial.

There are plantations ten to twenty miles remote from railroads and rivers where before the war you could find from fifty to three hundred negroes; now they are the *huntsman's home*. He kills his game on lands that in days gone by would produce from one-half to one bale of cotton to the acre.

Negroes, appreciating the disadvantages of living away from them, have clustered around towns, etc. You would infer from this, as some of our Southern Democratic friends would tell you, that it would swell our population proportionally; but that this is not so, is my observation. Our white population is gradually increasing, but the reverse is the case with the negro.

(Our correspondent here inserts a table of the vital statistics of one of the smaller Southern cities, which shows a death-rate among the colored twice as great as that among the whites, and adds:)

The negro race in this section, there is no doubt, is gradually diminishing. An honest vital statistic report would verify this assertion. I have very little hope for the colored doctor in the South. Some few will succeed, but many will fall by the wayside of temptation. They will have to live out of (so to speak) a penniless community. They can never attain eminence and have the confidence of their race, because of their poverty, being unable to keep up appearances. You know this is a peculiar characteristic of the colored man. He wants to imitate his employer, even in getting a doctor. Pardon me for writing so long a letter, but this is a subject in which I have been long interested. Respectfully,

[illegible]

OTOLOGY AT THE UNIVERSITY OF AMSTERDAM.

A MODIFICATION OF [illegible] INSUFFLATION — SOUTH-BRUNS-IN — A SIMPLE INSUFFLATOR — ACCIDENT IN TONSILOTOMY—INSPISSATED CERUMEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The methods of Dr. A. Guye, Professor of Otology in the University of Amsterdam present some novel and interesting features, which are here reproduced for the readers of THE MEDICAL RECORD.

The clinic is held at the Binnen Gasthuis (Central Hospital) of Amsterdam, at the head of the canal Oude Zyds voor Burgwal, on Monday and Friday, from four to five P.M. From thirty to forty patients are generally in attendance. There are fewer that are able to pay than with us. At the first visit patients are examined with more care than I have observed at many clinics. At the subsequent visits they are handled rapidly, as from the nature of the cases the treatment is more or less routine. The name, age, and other items, are entered in a register, and also a drawing of anything of interest about the membrana tympani. Before Politzerization the professor always cleanses the nares, using a small bulb-syringe, with water at a temperature of 70° or 75 F., as he thinks the use of water at a higher temperature predisposes to attacks of acute coryza.

After two or three syringefuls are thrown into the nostrils the patient is directed to blow his nose, after which the bag is used in the usual manner. It is surprising that nature's method of cleansing the upper respiratory tract

[1] Referring to THE RECORD of March 27, 1886.

is not more largely used. In very young children he has modified Politzer's method by having an assistant pour a teaspoonful of water into the mouth of the crying cherub, who involuntarily swallows it, when he at once presses the bag.

The so-called adenoid vegetations are scraped away with the finger-nail, scraping from before backward. A scraper is sometimes used for the same purpose, which is a device of the doctor's invention. It consists of a handle long enough to reach the pharyngeal cavity, to which is attached, at right angles, a blade one inch long, one-fourth inch wide, and one line in thickness, the end of which is bevelled to a dull edge. With this instrument no harm can be done to the normal mucous membrane. It would probably be more effective if it were a little wider.

Chronic nasal catarrh he treats with :

℞. Ammonii chloridi 40.00
Sodii chloridi 80.00
Aquæ 400.00
M. et ft. sol.
Sig.—Teaspoonful in a glass of water to wash the nose, t.i.d.

For this purpose the patient is furnished with a bulb-syringe, and instructed to cleanse the nasal cavity in the manner above described. After cleansing the nostrils a snuff is insufflated. The doctor's insufflator, for simplicity and cheapness, cannot be excelled. It consists of a rubber tube, into each end of which a goose-quill is inserted. It answers the purpose as well as more elaborate instruments.

Mouth-breathing he treats with a contra-respirator. This is a simple but useful instrument, consisting of an oval piece of leather, to which tape is sewed, so that it may be tied over the mouth. These patients are furnished with a copy of the following circular, which is printed in Dutch, English, German, and French :

"THE CONTRA-RESPIRATOR AND RESPIRATION THROUGH THE MOUTH.

"Respiration through the mouth is a bad habit which is very common, the pernicious consequences of which have been shown by Mr. Catlin in his book 'Shut your Mouth;' by Mr. Paul Neimeyer, in Magdeburg, and others. The habit originates, generally, from a catarrh of the nose or cold in the head. Respiration through the nose costs them too much effort, and the mouth is opened accordingly. But when the passage through the nose is free again, the bad habit very often persists, and causes a fresh catarrh or swelling of the nose, because the normal quantity of air is not passed through it. The results of respiration through the mouth are injury to the teeth by exposure to cold and dry air; various diseases of the throat and chest, by the dryness of the mucous membrane of the throat, and by the small foreign bodies, dust, smoke, etc., which would otherwise be kept back by the mucous membrane of the nose. As a sequel to the catarrh of the nose and throat, very often follow deafness, and other diseases of the ear.

"The consequences of respiration through the mouth are specially injurious during sleep, because then the disagreeable and pernicious dryness is not felt, and can accordingly attain a much higher degree. The bad influence of sleeping with the mouth open can be seen daily by comparing the calm, refreshing sleep of one sleeping with his mouth shut, with the restless, painful sleep, often degenerating into a nightmare, of another sleeping, ofttimes snoring, with the mouth wide open.

"The contra-respirator is used very effectually against the bad habit, especially in the beginning. When in bed fasten it so that it very slightly presses on the lips. Should it prevent sleep, take it off after some time, say ten minutes, trying it every night for the same length of time.

"After a few days you fall asleep easily with it on, and after a shorter or longer period you learn to sleep with your mouth shut without the use of the contra-respirator.

"When there are obstructions in the nose, which prevent absolutely respiration with the mouth closed, of course the use of the contra-respirator alone is not sufficient, but a medical man must be consulted, who should examine and treat the mucous membrane of the nose. By neglect polypi and other diseases of the nose may be occasioned."

For excoriations about the nose :

℞. Tinc. benzoin 1.00
Vaselinæ 10.00
M. Sig.—For external use.

Pleasant for its agreeable odor. Note that the compound tincture is not to be substituted in the above formula. It is also useful in chapped nipples.

In performing a tonsillotomy on a young man, about seventeen years of age, with the Fahnestock instrument, the blade broke when the operation was about half completed. The instrument was fast in the tonsil, and could not be with drawn until it was dissected out with a scissors. On examination it was found that about one-half inch of the blade was missing. The patient remained in Amsterdam until the fourth day. Returning home on the boat, he was seized with a pain in the bowels, and a diarrhœa. He passed several stools, which he did not examine, as he had been instructed. The missing part of the blade was never discovered. The doctor had had a similar experience before, but did not think that two accidents in as many thousand cases was any argument against the use of the instrument.

Inspissated cerumen, says the doctor, is caused, not by increased secretion, as the books say, but by diminished secretion. The wax is too dry to be removed by natural means. The accumulation is but a symptom of a disease of the middle ear. After it has been removed several times the patient presents himself with the usual deafness, but no wax. To prevent the accumulation olive oil is dropped into the meatus, three drops once a week.

As a diagnostic point, headache due to congestion of the frontal sinus is relieved by Politzerization. This is cured by treating the nose. In using the Politzer bag the impulse is normally greater in the ear on the side opposite to the nostril in which the bulb is introduced. If it is felt in the ear on the same side, it is due to some pathological condition.

FRANK T. SMITH, M.D.

AMSTERDAM, HOLLAND, March 1, 1886.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 11, *to April* 17, 1886.

PATZKI, J. H., Captain and Assistant Surgeon. Relieved from duty at Jackson Barracks, La., and ordered for duty as Post Surgeon at Mount Vernon Barracks, Ala. S. O. 75, Department of the East, April 12, 1886.

HOFF, JOHN VAN R., Captain and Assistant Surgeon. Leave of absence extended eleven months, with permission to leave the United States. S. O. 85, A. G. O., April 12, 1886.

BARNETT, RICHARDS, Captain and Assistant Surgeon. Granted leave of absence for two months. S. O. 16, Division of the Atlantic, April 12, 1886.

WALES, PHILIP G., First Lieutenant and Assistant Surgeon. Granted leave of absence for two months. S. O. 85, A. G. O., April 12, 1886.

New Instruments.

IMPROVED VAGINAL SPECULUM.[1]

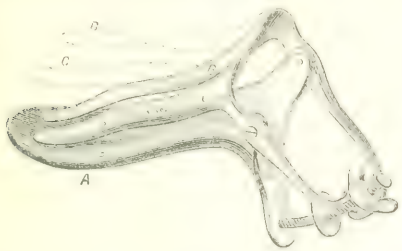
By JOHN BLAKE WHITE, M.D.,

VISITING PHYSICIAN TO THE HOSPITAL, BLACKWELL'S ISLAND, N. Y.

THE speculum we use to-day is a composite instrument, the result of successive improvement at the hands of experts.

Although important features about it have from time to time been added, not one alone of these instruments can be relied upon to the exclusion of the rest. There is, therefore, latitude yet open for the exercise of invention to those who are in the habit of employing the various forms of this essential auxiliary to diagnosis and treatment of uterine diseases.

Having been, therefore, by experience, made sensible of the want of certain features about even the most practical form of speculum now in use, I ventured into the field of invention and directed one of the following pattern to be made. Its success in my own hands, and that of a few of my professional friends, for the past three years, in facility of introduction, in readiness of adaptability and perfect command of the parts to be examined and treated has been so satisfactorily demonstrated that I have esteemed it a duty I owed to the profession to place it at the option also of those from whom I have at various times received similar favors :



The lower blade, *A*, is so constructed that, when introduced, it follows the posterior vaginal wall, which, owing to the concavity of the sacrum, is curved, and the cup-shaped extremity rests directly behind the cervix uteri.

If the uterus is displaced, the curved end of the speculum will assist in bringing the cervix into view. By its aid the vagina is more easily distended posteriorly and inferiorly. The two upper blades, *B* and *C*, are concavo-convex, so that full dilatation may be effected superiorly at points where least resistance is offered by the anatomy of the region.

The part of the pelvis through which the vagina courses and admits a speculum, contains no organ or tissues that can possibly suffer by considerable distention of the vagina. This fact is well shown during the act of parturition.

The Sims speculum is rendered far more useful, constructed in accordance with this natural vaginal curve posteriorly.

[1] Presented at a meeting of the Manhattan Medical and Surgical Society, February 8, 1886.

The cylindrical specula are also more useful when made to conform more fully to this posterior vaginal curve. The improved Nott's speculum has another advantage in that the two upper blades, *B* and *C*, are so arranged that they admit of independent action, which device enables the operator to lift one or the other lateral half of the vagina as he may desire. This mechanism facilitates the search for the cervix uteri, especially in displacements.

The introduction of the uterine sound, as well as tents, is rendered more practicable when this curved speculum is used, and local treatment of the endometrium can be far more thoroughly and satisfactorily accomplished. When this instrument is closed for withdrawal, the folds of the vaginal mucous membrane are less apt to be pinched than with the other trivalve specula. A smaller-sized instrument than the one presented should be used in nulliparous vaginæ.

THE LATE DR. S. OAKLEY VANDER POEL.—At a recent meeting of the Faculty of the Medical Department of the University of the City of New York, the following minute was adopted :

Whereas, The Faculty has heard with the deepest regret the unexpected announcement of the death of their late colleague, Professor S. Oakley Vander Poel, M.D., and hereby tender their sincere sympathy to the members of his family, in the great loss which they have sustained;

Resolved, That the distinguished abilities of Dr. S. O. Vander Poel, and the services which he rendered for so many years, and with such universal acceptance to the whole country, in the important public trusts which he held as a medical man, rendered him peculiarly well-fitted for the duties of the Chair of Public Hygiene, which he held in this College, and which he discharged to the great advantage of the institution :

Resolved, That while his high qualities as a man commended him to the esteem of all, his personal characteristics caused his friendship to be highly prized, and will make his loss to be long felt by all who came into relations with him.

CHARLES INSLEE PARDEE,
Dean.

THE LATE DR. GASPAR GRISWOLD.—At a meeting of the Alumni Association of the Bellevue Hospital Medical College, held Saturday, April 3, 1886, the following resolutions were adopted :

Whereas, It has pleased Almighty God in his mysterious Providence to remove by death one of our number, Gaspar Griswold, M.D., M.R.C.S. :

Resolved, That the Alumni Association of the Bellevue Hospital Medical College hereby expresses a sense of its great loss in the death of Dr. Griswold. Although

young in years he had already taken a prominent place in the profession, and gave promise of great usefulness and eminence. He was direct and practical as a teacher, genial in his manner, kindly and considerate toward others, an honor to his Alma Mater and the medical profession. This Association particularly feels that in his early death it has lost a much respected and most valuable member.

Resolved, That the Association tender most respectfully to the family of Dr. Griswold this expression of its profound sympathy.

Resolved, That a copy of these resolutions be sent to the family of the deceased, and that they be furnished to the medical journals of this city for publication.

A. A. Smith,
V. P. Gibney.
L. Putzel,
R. Van Santvoord, M.D., *Committee.*
Recording Secretary.

The New Name for Tartar on the Teeth.—There once was a trouble known as tartar on the teeth, but of late some enterprising dentists have named this "Rigg's Disease," a condition requiring "treatment" in place of the old-fashioned scraping off the tartar.

Syphilis in the Thirteenth Century.—It is commonly believed that syphilis first made its appearance in Europe toward the close of the fifteenth century, about the time of the discovery of America by Columbus, and it has even been said that it was brought from the new world by some of the virtuous followers of the great discoverer. Some recent researches of Dr. Leon Duchesne would seem to show, however, that its origin was at least two centuries earlier than this (*Journal de Médecine de Paris*). In a surgical work compiled by Theodoric, a Dominican monk, in 1250, a chapter is devoted to the *malum mortuum*, and a treatment by means of mercurial inunctions is recommended. Lanfranc, of Milan, in his treatise on surgery, composed in 1296, has a chapter on "Chancre and Ulcer of the Penis in Man." Guillaume de Salicet and Gérard, in their works on surgery, written during the same century, also describe a disease which could be no other than syphilis.

Breathing Cold Air in a Warm Room.—An apparatus is advertised in Europe by which a person is enabled to breathe the air from without while sitting indoors in a warm room. It consists of a simple tube, communicating through the window with the external air, to one end of which an attachment to fit over the mouth and nose is attached. The inventor claims that, as tubercle bacilli are destroyed by a low temperature, so pulmonary phthisis may be cured by breathing frosty air through this apparatus.

Another Cure for Rabies.—A Hungarian journal states that seventeen individuals were recently bitten by a mad dog in the town of Varadino. A peasant named Nemcsics offered to cure them, and as they were unable to bear the expense of a visit to Pastëur, they accepted his offer. One of the number relates that the peasant made them drink a fluid of a red color, tasting like brandy, and containing what seemed to be little pieces of Spanish fly. In a short time they were seized with excruciating pains, had attacks of furious mania, and finally became unconscious. When they came to themselves they felt great hunger, combined with a repugnance to every kind of food. Nemcsics thereupon declared that they were cured, and up to the time of the report none of them had had any symptoms of rabies.—*La Riforma Medica.*

A Singular Case of Deep-Sea Diving Drink.—M. Legrand du Saulle, in his work on legal medicine, reports a little-known fact relative to the private life of Peter the Great. On a certain occasion, shortly after his second marriage, this monarch desired to send a very urgent message to the Czarina, and entrusted it to a Frenchman named Villebois to deliver in person. The weather was very cold, Villebois liked his vodka, and when he arrived at his destination he was very drunk. The Czarina was in bed, and her ladies retired when the messenger from the emperor was introduced. At the sight of the young and beautiful woman he became furious and precipitated himself upon her, and although assistance was speedily obtained the honor of the absent husband was not saved. Villebois was put in the lock-up, and at once fell asleep, and could not be aroused even after the Czar, who had been summoned in great haste, arrived. Peter, who had good reasons to excuse drunkenness, contented himself with sending the Frenchman to the galleys. In six months he granted him a pardon and reinstated him in his former office.

Congress of Russian Physicians.—On January 7th (December 26th, O. S.) the first Congress of Russian physicians was opened with much ceremony in St. Petersburg. The proposal to hold an annual convention of this sort has been under consideration for a number of years, but it is only now that the project has been realized. The Congress will be held each year, alternately in Moscow and St. Petersburg. The President of the Congress was Professor Krassovski; Dr. Ebermann, Secretary; Dr. Sutugin, Treasurer. The meeting was closed on January 12th (December 31st)

Soap in the Preparation of Certain Ointments.—When it is desired to combine oil of cade with vaseline or glyceride of starch, it is impossible to make a homogeneous mixture. But, according to Pierre Vigier (*Gazette Hebdomadaire de Médecine et de Chirurgie*), a perfectly smooth ointment can be made by adding one part of soap and two of water to thirty parts of the ointment desired.

A Premium for Large Families.—A decree was recently enacted in France reaffirming the law of the 29th Nivôse, year XIII., according to which every father of a family having seven living children may have one of his sons educated at the expense of the State. The object, of course, is to increase the population of the country, and the immediate occasion of the decree was the publication last year of statistics showing a large falling off in the average size of families in France.

An Opening for Physicians in India.—According to a letter in an Austrian journal, a most promising field for medical practice exists in India, especially in the inland parts of the peninsula. There is plenty of sickness, and physicians receive large fees. A knowledge of the language, sufficient for all practical purposes, is readily acquired, and beyond that, the writer states, nothing is needed for the acquisition of a large practice and a handsome income.

The Poetry of Attenuation.—In The Record of October 24th appeared the following:

Little drops of water,
Little grains of milk,
Make the little doctors
[illegible]

A correspondent from Massachusetts supplements this:

Precious little bottles,
Sitting in a row,
Filled with potent liquid
[illegible]

[illegible]
Humble though it be,
Makes the tenth dilution
When poured into the sea.

Of all the gulls delusive
The greatest is to know
Where lies the healing power
In a drop of H_2O.

Vol. 29, No. 18 NEW YORK, MAY 1, 1886 Whole No. 808

Original Articles.

THE MALARIAL "GERM" OF LAVERAN.

BY GEORGE M. STERNBERG, M.D.,

THE space and time at my disposal will not permit me to preface this paper by a recapitulation of the arguments in favor of the view that the malarial fevers—properly so called—are due to the presence, in the body of those attacked, of living "germs" or micro-organisms. This view was suggested by Lucretius (95 B.C.), and was ably advocated in this country as long ago as 1859 by Dr. Mitchell, of Philadelphia. Nor can I refer to the earlier claims to the discovery of a specific malarial germ. But before proceeding to a consideration of the "malarial germ of Laveran," the discovery of which was announced in a communication to the French Academy of Medicine, dated November 23, 1880, I desire to refer briefly to the claim made during the previous year (1879) by Professor Klebs, the distinguished German pathologist, and Professor Tommasi-Crudeli, of Rome. These gentlemen, as a result of an experimental research made in Rome, with material obtained from the malarious marshes in the vicinity of that city—Pontine Marshes—announced the discovery of their *bacillus malariæ* in a communication published in German in Klebs' *Arch. f. exper. Path. u. Pharmakol*,[1] and in Italian in the "Trans. R. Acad. Lincei." [2] This alleged discovery attracted great attention at the time, and considerable evidence, which seemed to strongly support the claim made, was subsequently offered by several independent observers—Marchiafava, Cuboni, Marchand, Ziehl, Ceri, and others. It is not surprising, therefore, that by many physicians the *bacillus malariæ* was accepted as a veritable contribution of modern science to our knowledge of etiology, and as entitled to rank with the spirillum of relapsing fever, the anthrax bacillus, and the tubercle bacillus of Koch, among the demonstrated disease germs. The fact that no well-informed person any longer maintains this view, shows how easy it is to be mistaken in estimating the value of experimental evidence, and of recorded microscopical observations, in this new and difficult branch of pathological investigation.

Soon after the publication of the memoir of Klebs and Tommasi-Crudeli, the writer, under the direction of the National Board of Health, made a series of control experiments in New Orleans, as a result of which the following general conclusions were reached:

"Among the organisms found upon the surface of swamp-mud, near New Orleans, and in the gutters within the city limits, are some which closely resemble, and perhaps are identical with, the *bacillus malariæ* of Klebs and Tommasi-Crudeli; but there is no satisfactory evidence that these, or any of the other bacterial organisms found in such situations, when injected beneath the skin of a rabbit, give rise to malarial fever corresponding with the ordinary paludal fevers to which man is subject."

"The evidence upon which Klebs and Tommasi-Crudeli have based their claim of the discovery of a *bacillus malariæ* cannot be accepted as sufficient; (*a*) because, in their experiments and in my own, the temperature curve in the rabbits experimented upon has in no case exhibited a marked and distinctive paroxysmal character; (*b*) because healthy rabbits sometimes exhibit diurnal variations of temperature (resulting, apparently, from changes in the external temperature) as marked as those shown in their charts; (*c*) because changes in the spleen, such as they describe, are not evidence of death from malarial fever, inasmuch as similar changes occur in the spleens of rabbits dead from septicæmia produced by the subcutaneous injection of human saliva; (*d*) because the presence of dark-colored pigment in the spleen of a rabbit cannot be taken as evidence of death from malarial fever, inasmuch as this is frequently found in the spleens of septicæmic rabbits." [3]

Notwithstanding the "confirmatory evidence" subsequently published by several Italian observers, the writer remained skeptical with reference to the *bacillus malariæ*; and in 1884, when my work on "Malaria and Malarial Diseases" was published, I was not prepared to admit that the more recently discovered germ of Laveran was entitled to any greater confidence. Referring to this I say:

"These observations of Laveran and of Richard are entitled to equal consideration with those of the Italian observers who find the *bacillus malariæ* in the blood of their malarial-fever cases in the vicinity of Rome.

"We cannot doubt that a true account has been given in both cases of what the observers believe they have seen. But there is a wide field for doubt as to the deductions made from the various observations recorded; for in microscopical studies of the blood made with high powers there is a great liability to error, and to misrepresentation of what is seen. We may question, for example, whether the belief of Laveran and Richard that the appearances noted by them are due to parasitic invasion of the blood-corpuscles is well founded, without calling in question the accuracy of their observations.

"As the Italian observers make no mention of the *oscillaria malariæ* of Laveran, and as the French observers seem not to have encountered the *bacillus malariæ*, each series of observations is, in a negative way, opposed to the other. It is evident, therefore, that physicians in this country who wish to know the exact truth as regards the nature of malaria will do well to investigate for themselves, or at least to encourage investigations at home by those who seem fitted by education and inclination [4] to undertake them." [5]

The argument here used as regards negative evidence from Italian investigators has no longer any force, for the discovery of Laveran is now confirmed by Marchiafava and his associate Dr. Celli.[6] The fact that Marchiafava formerly published observations which he supposed to be in favor of the alleged discovery or Klebs and Tommasi-Crudeli, and that so far as national or personal prejudice can influence a scientific man he would naturally have a bias in favor of the *bacillus malariæ*, gives to his evidence relating to the parasite described by Laveran especial value.

The object of the present paper is to give an account of the researches referred to, and to introduce to the

[illegible]

[illegible] especially to search for the malarial germ of Laveran, but has not had an opportunity of meeting with typical cases since the date mentioned (until quite recently in Rome), having been stationed for three years at an extremely healthy post in [illegible]

[illegible]

[illegible]

[4] Nuove richerche sulla infezione Malarica, Archiv. per le Sci. Mediche, vol. [illegible]

profession in this country this interesting blood-parasite, which was demonstrated to the writer, by the gentlemen named, during a recent visit to Rome, and which there is good reason to believe is the long-sought malarial germ.

It will first be desirable to call attention to certain dark-colored granules and irregular masses of pigment which have long since been recognized by pathologists in the blood and tissues of the victims of malarial disease, and which are considered pathognomonic of such affections. The earlier observers were in doubt whether the pigment-granules found by them in the blood during life, or post-mortem, were formed *in situ* or distributed from the spleen, where similar pigment is found in considerable quantity. The latter view was supported by Virchow,[1] by Frerichs,[2] and by Mosler.[3]

The first-named author having discovered numerous pigmented cells in the blood and in the spleen of an individual, who died of dropsy resulting from repeated attacks of intermittent fever, maintained that the pigment in the blood has its origin in the spleen. Frerichs, in supporting the same view, supposes that this formation of pigment in the spleen is peculiar to malarial fever, because some peculiar chemical change in the "splenic liquid" occurs in this disease, as a result of which the red corpuscles are destroyed in the enlarged and hyperæmic organ and the black pigment produced.

On the other hand, Arnstein[4] maintains that the pigment is formed in the blood in circulation during a febrile access, and that the melanæmia is primary and the accumulation of pigment in the spleen and other organs secondary.

According to this author the pigment-granules are produced by some change in the hæmoglobine of the red corpuscles, which are destroyed during the febrile access; these granules are taken up by the white corpuscles, in the interior of which they are found in masses of various sizes; and, finally, these white corpuscles are destroyed in the spleen and other organs where their burden of pigment is deposited.

Recent investigations, and especially those of Laveran, of Marchiafava and Celli, and of Councilman and Abbott,[5] indicate that this is the true explanation of the melanæmia, and of the pigmentation of the spleen and other organs. At all events it is beyond doubt that pigment-granules are formed in the blood in large numbers during a fatal attack of pernicious malarial fever, for they may be plainly seen *in the interior of the red blood-corpuscles*, lying in the capillaries of the brain, the liver, and other organs, when properly-made sections are examined under the microscope. The writer has been able to verify this fact to his entire satisfaction in sections prepared by Dr. Councilman from the two cases referred to in his interesting paper[6] and also in sections exhibited to him while in Rome by Drs. Marchiafava and Celli.

The distribution of the pigment-granules in the capillaries of the brain is shown in Fig. 1, which we take from the late work of Laveran.[7] The dark masses distributed through the capillaries are not single granules, as would appear from the figure, but collections of pigment-granules included in red blood-corpuscles, the outlines of which are not seen, but the presence of which is indicated by the separation of the little masses by clear spaces, and their rather uniform distribution in the capillary vessels.

Upon examining a section of this kind with a good objective we ascertain not only that these pigment-granules are included in the red blood-corpuscles, but also that they are included in a hyaline mass which seems to be differentiated from the substance of the corpuscle. These hyaline bodies were described by Councilman and Abbott in their paper referred to, and were demonstrated by these gentlemen to the writer in numerous sections. At the close of their paper the question as to whether these hyaline bodies are organisms is discussed, but no definite conclusion is reached, and indeed it may be

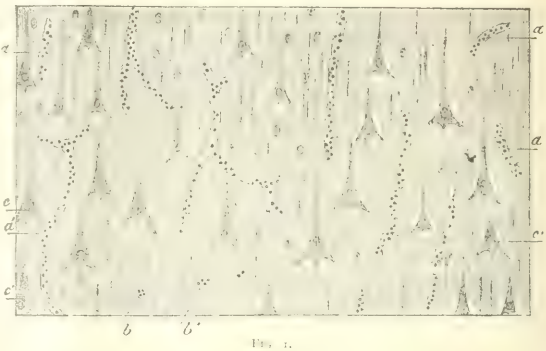

Fig. 1.

doubted whether this question could be settled by the examination of post-mortem material alone. Marchiafava and Celli find the same hyaline bodies in the interior of the blood-corpuscles in similar sections of brain-tissue, etc., from cases of pernicious malarial fever, and they have been successful in differentiating these masses in a most satisfactory manner by the use of staining reagents—methylene blue, alkaline, in saturated alcoholic solution, or an aqueous solution of visuvine. Moreover, the gentlemen referred to have demonstrated the presence of similar hyaline bodies, in the interior of the red blood-corpuscles, in certain cases, without any accompanying pigment-granules, showing that while the pigment may be secondary and a result of their presence, they are not dependent upon the presence of pigment. In Fig. 2 we have these bodies represented in the

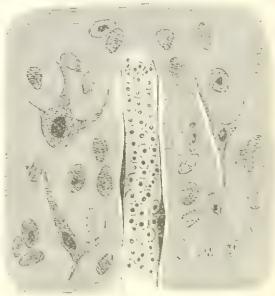

Fig. 2.

interior of the red blood-corpuscles in a capillary of the brain, from a case of "comatose pernicious fever." The figure is copied from the memoir of Drs. Marchiafava and Celli upon the "Alteration of the Red Blood-globules in Malarial Infection and Genesis of Melanæmia."[1]

In the memoir referred to the hyaline bodies appear as pale blue masses in the interior of the corpuscles, the figure having been made from a preparation in which they were stained with methylene blue. In reproducing this figure in the present paper, we must content ourselves with plain black and white, and it is to be feared that the woodcut will fail to convey the idea of hyaline masses, hardly to be distinguished except by the use of

[1] Trans. R. Acad. Lincei, 1884.

[5] Loc. cit.

a suitable staining reagent, and differing essentially from the pigment-granules shown in Fig. 1. When pigment is also present, it will be remembered that the granules are included in this hyaline mass.

A comparison of the figures which illustrate the paper of Councilman and Abbott,[1] heretofore referred to, will show that in the two cases so well recorded by these gentlemen the same hyaline bodies were found in great numbers; and a reference to the text shows that they also found the hyaline bodies independently of pigment-grains, and that "sometimes they were free"—*i.e.*, not included in the blood-corpuscles. They say: "From the great numbers of these masses in the brain they could be studied better here than in any other place. It could be distinctly seen that they were stained and appeared to be composed of a hyaline or very finely granular substance. Their diameter, as said before, was about one-third that of a red blood-corpuscle. The pigment within them presented the same appearance and arrangement as in the spleen. In some, the circular arrangement of the pigment-granules was very obvious. There was scarcely a capillary in the gray substance of the brain that did not contain these bodies in greater or less numbers. Some of the vessels were filled with them, and no corpuscles could be seen. Others contained both the hyaline masses and blood-corpuscles. At various places, in stainings made both with Bismarck brown and gentian violet, hyaline masses were found containing *no* pigment, which stained in the same way, and were of the same shape and size as those which contained the pigment. Others were found which contained but one or two pigment-granules."[2]

It is evident that the question as to the nature of these so-called hyaline bodies is likely to have a very important bearing upon the etiology of the malarial fevers; for if they are in truth parasitic organisms, their position in the interior of the red blood-corpuscles, their presence in vast numbers in quickly fatal "pernicious" forms of malarial disease, and their association with the pigment-granules, which are recognized as pathognomonic of malarial poisoning, makes it appear extremely probable that they bear a causal relation to the morbid phenomena which constitute the disease. That the red blood-corpuscles are destroyed on an extensive scale during an intermittent paroxysm has been repeatedly demonstrated by actual counting, and it is a matter of common experience that a series of such paroxysms induces profound anæmia. This result will be easily comprehended if we have indeed to deal with a parasite which invades or destroys the red blood-corpuscles. The writer, from a general review of the evidence, and as a result of personal observations recently made in Rome, through the courtesy of Drs. Marchiafava and Celli, is inclined to believe that this is the case, and confidently anticipates that, when the opportunity presents itself, he will be able to verify the fact in this country by direct observations upon blood drawn during life from patients suffering from typical forms of malarial fever.

There can be no doubt that the hyaline bodies heretofore referred to as found within the red blood-corpuscles in sections of the brain, etc., obtained from fatal cases of pernicious fever, correspond with similar bodies described by Laveran, and found by him in blood freshly drawn from the finger of patients suffering from intermittent fever.

As we have now arrived at the point where it becomes necessary to refer more explicitly to the work of Laveran, I shall take the liberty of quoting somewhat extensively from his book, published in Paris in 1884.[3] In the Introduction to this work the author says:

"This work is the fruit of five years' researches pursued without remission in Algeria; in writing it my principal object is to make known the parasites which I have been fortunate enough to find in the blood of patients attacked with malarial fever.

"At the time of my arrival at Bone, in the month of September, 1878, I did not entertain the hope of discovering the causes of 'paludism,' and my first labors were not directed in this direction; I occupied myself at the outset with the clinical history and pathological anatomy of the malarial fevers, seeking to free myself from preconceived ideas and from the influence of all of the classical theories.

"An analysis of the anatomical lesions observed in patients who had succumbed to a pernicious access, or to malarial cachexia, showed me that the characteristic lesion, and the only one constant in malarial poisoning, consisted in the presence of pigmented elements in the blood. These pigmented elements were known; they had been, in particular, very well described by Frerichs; but their origin and their nature were yet very obscure. It was while studying the mode of formation of these pigmented elements in the blood that I was brought to recognize their parasitic nature.

"On November 6, 1880, while examining the blood of a patient under treatment for intermittent fever in the military hospital of Constantine, I recognized for the first time the existence of mobile filaments which were attached to the pigmented bodies, and of which the animated nature was not doubtful. I had at this moment the intuition that I was in presence of the veritable malarial germ, '*microbe du paludism*,' and all the facts which I have observed since have gone to confirm this first impression.

"I have verified the presence of this particular organism in four hundred and thirty-two patients attacked with different forms of malarial disease, and I have never encountered these microbes in subjects attacked with other diseases.

"All of the military physicians who at Constantine have interested themselves in my researches, and who have done me the honor to frequent my laboratory, have been able to recognize the existence of this microbe, and to verify the facts which I have stated. . . .

"In 1882 I made a voyage to Italy, for the special purpose of seeking in Rome the parasites which I had observed in Constantine, and I have been able to convince myself that the blood of fever patients from the Roman Campagna contains microbes identical with those which I have described in the blood of similar cases in Algeria. . . .

"The search for the malarial parasite requires, it is true, a certain familiarity with the use of the microscope in general, and with the examination of the blood of malarial cases in particular, but these are difficulties which it is easy to surmount with a little patience."

We pass now to Chapter III., in which a detailed account of the morphology of the parasite is given, together with explicit directions for finding it. As we hope that the present article may induce microscopists in our own country, who are favorably located for such researches, to attempt to verify the alleged discovery, we shall quote from this chapter so much as seems necessary to serve as a guide for such researches.

"The technique which permits of the observation of the parasitic elements in the blood of malarial cases is very simple; it is, however, necessary here to enter into some details for the search is not unattended with difficulties.

"1st. *Choice of patient.*— . . . It is at the outset of the access of fever, or during the hours which precede the invasion of the febrile paroxysm, that the parasites are found in the greatest number in the blood, and that they are consequently most easily found. It will be best to choose a patient who has already had several malarial attacks and who is decidedly anæmic; the parasites are usually numerous in these cases and more easy to find, inasmuch as the blood is poor in red corpuscles; it will, above all, be necessary to choose a patient who has not taken sulphate of quinine for some time.

"2d. *Technique for the preparation of the blood.*— . . . Prepare two thin glass covers, and two glass slides, which

[1] Op. cit. [2] Op. cit., p. 413. [3] Op. cit.

are very level; it is well to wash these first with water and then with alcohol, although the microbes of malaria are so characteristic that there is little danger that they will be confounded with dust or with the spores and bacteria suspended in the atmosphere, and which may fall upon the preparation.

"One preparation will usually suffice for the examination of blood, but it is wise to make two, as one may not be satisfactory on account of the thickness of the layer of blood or for some other reason.

"After having washed one of the patient's fingers, first with water and then with alcohol, it should be compressed at the base, and a puncture made with a new needle, or with a perfectly clean lancet, at the extremity —*la pulpe*—care being taken to choose a locality where the epidermis is not too thick. The drop of blood obtained in this way should be of moderate volume; when the skin is dry, the drop takes a rounded form; when the weather is warm and the skin is covered with sweat, or when one proceeds to the examination of a patient who is in the sweating stage of an intermittent paroxysm, the drop of blood spreads out and mingles with the perspiration. In this case it is necessary to dry the skin with care and collect the blood very rapidly.

"The drop of blood which is formed at the extremity of the finger is collected by bringing in contact with it one of the glass slides; the slide should not touch the skin; the little drop of blood adheres in part to the glass slide and is to be immediately covered with one of the thin glass covers previously prepared. It is well to slightly moisten the slide and cover-glass by breathing upon them; the cover-glass is applied to the drop of blood in such a manner as to form at first an angle of about 45°, and is then quickly lowered and at the same time made to slide upon the glass slide in order that the blood may be spread out without the interposition of any air-bubbles.

"The preparation should present a very pale color; if the layer of blood is too thick, it will be necessary to press gently upon the cover-glass, and afterward to wipe away the blood which is forced out from around its margin; care must be taken not to use too strong a pressure, as this would destroy the parasitic elements, or at least alter their aspect.

"At the outset of my researches I always took the precaution to place paraffine around the margin of the cover-glass; this precaution is not essential. The blood dries rapidly upon the edges of the preparation, especially when the air is warm and dry, and forms a solid cement which prevents the central portion from drying. At the end of twenty-four or of forty-eight hours one generally finds the central part of a preparation made in this way still liquid. . . .

"The blood ought to be examined pure, without mixture with any liquid, for it is in blood-serum that the parasites retain for the longest time their vitality after having been withdrawn from the circulation." . . .

"There is no advantage in taking the blood for examination from one part of the body rather than from another. . . . . The parasitic elements are found in the blood coming from natural hemorrhages—epistaxis, hæmoptysis, hæmaturia, etc. I have looked for them in vain in the serum obtained from the vesicles of labial herpes, and in the urine of malarial patients.

"3d. *Mode of examination of the preparations.*—An amplification of 400 to 500 diameters suffices for the observation of all the details presented by the parasitic elements found in the blood of malarial patients. . . . In the examination preference should be given to those parts of the preparation in which the red corpuscles lie flat and form but a single layer. . . . The corpuscles which adhere strongly to each other at the moment when the blood is drawn frequently become isolated in a few minutes, and present themselves *de face;* the examination of the blood is therefore, in general, more easy after ten or fifteen minutes, or even at the end of half an hour. . . . The search is rendered somewhat difficult by the fact that in general the parasitic elements are not found in great numbers in the blood. One finds sometimes as many as eight, ten, or fifteen parasitic elements in a single field of the microscope, but this is a somewhat rare event, and the observer should have for this study a provision of patience. In the cases, sufficiently frequent, in which the parasites are not numerous, it will often be necessary to make a prolonged examination—ten or fifteen minutes, or even more—in order to discover them.

"The pigment-granules which are usually found in the parasitic elements serve to call attention to them; the parasites themselves are so transparent that it would be difficult to see them if they were not pigmented; we shall see further on that the mobile filaments which represent the most perfect form of the malarial microbe, and which do not include any pigment, are only visible when in motion. The observation of the movements of these filaments, which is so interesting, is particularly difficult. It often happens that these movements are arrested under the influence of the cooling which the blood undergoes upon being withdrawn from the vessels, and only reappears after an interval of a quarter of an hour or half an hour. Warm weather is the most favorable for the observation of these mobile filaments; or one may make use of a hot stage, the temperature of which should be 37° to 38° C."

Description of the microbes of malaria.—"The parasitic elements present themselves under several forms, which appear to correspond with different phases of the evolution of the same parasite. These forms, to the number of four, were described in my first communications relating to the malarial parasite under the following names, which I think it well to preserve in order to prevent confusion: cellular bodies—*corps kystiques*—No. 1 and No. 2, or simply bodies No. 1 and No. 2; mobile filaments; and body No. 3, which seems to be simply the cadaveric form of bodies No. 1 and No. 2.

"To this enumeration we might add the leucocytes containing pigment which borrow the pigment grains with which they are charged from the parasitic elements undergoing destruction, and which consequently are very characteristic of malarial disease."

"*Cellular bodies No. 1.*—These are cylindrical elements, having pointed extremities, most frequently curved in the form of a crescent, and pigmented toward the centre as shown in the following figure."

FIG. 3.—A, B, bodies No. 1 with pointed extremities. C, body No. 1 attached to a red blood-corpuscle. E, oval body, intermediate between No. 1 and No. 2. (Magnified about 1,000 diameters.)

"The length of these bodies is from eight to nine micromillimetres, the diameter about three micromillimetres in the broadest part. The extremities are sometimes pointed (A, B, Fig. 3), sometimes more rounded (D). The contour is generally indicated by a single delicate line; but it is easy to verify a double contour in certain preparations. These bodies are transparent, and colorless, except toward the central portion, where there are always some pigment-granules more or less agglomerated. Occasionally the pigment may be situated at one of the extremities. One may often perceive on the concave side a very fine line, which seems to unite the extremities of the crescent (B, Fig. 3). When one of these bodies is attached to a blood-corpuscle (C, Fig. 3) the extremities of the crescent pass the line of the contour of the corpuscle; the adhesion to the corpuscles is not strong, and appears to be purely accidental. . . . Beside these cylindrical elements of crescent shape are found almost always oval bodies (E, Fig. 3), which seem to be inter-

mediate forms between body No. 1 and body No. 2, which will be described further on; in these oval bodies the pigment grains are often arranged in the form of a crown, as in body No. 2. These bodies No. 1 do not appear to be endowed with movement, they do not change place in the field of the microscope, and when their form is modified it is in a very gradual manner; one may follow the transformation of these cylindrical bodies with pointed extremities to an oval and then to a spherical body. . . . In general it will be found that at the end of twenty-four or forty-eight hours these bodies, No. 1, have taken an irregularly spherical form. In the cadaver the bodies No. 1 change their form still more quickly than in the fresh blood; in order to find them it is necessary to collect the blood shortly after death."

"I will attempt further on to determine the conditions under which one meets these bodies No. 1 in the blood of malarial patients. It will suffice to say here that *the presence of these elements in the blood is much less constant than that of body No. 2*; if I have described them first it is in order to preserve the order which I have adopted in my first publications. Sometimes these bodies No. 1 are not found at all in blood rich in parasitic elements (bodies No. 2, and mobile filaments); sometimes, on the contrary, the blood only contains these bodies; in certain cases these elements exist in very great numbers in the blood; it has several times happened to me to find ten or twelve in a single field."

(To be continued.)

UNUSUAL CAUSES OF COUGHING.[1]

By CLARENCE C. RICE, M.D.,

NEW YORK.

It is the most important, and frequently the most difficult, task of the physician to ascertain the causes which produce coughing; to define exactly the locality upon which the irritant is at work. I wish to speak now only of those varieties of cough which are produced by disturbances in the upper portions of the air-passages, leaving out of consideration cough as associated with chest disease. Here it is but one of the many symptoms of the general disturbance, and it can be controlled with the other manifestations. Its importance, too, is outweighed by the constitutional condition of the patient, which may threaten to produce a fatal result. It is not the cough which is to be cured in pneumonia and phthisis, but the abnormal condition of the lungs or the associated bronchial catarrh which cause the coughing. On the other hand, there are many patients who consult a physician with whom the prominent and sometimes the only symptom is an aggravating, teasing cough. This is the only complaint, and the physician's aid is sought solely for relief from this annoyance. It is not enough in these cases to examine the throat and lungs critically, and to assure the visitor that his respiratory tract is healthy, and therefore it is useless and unnecessary for him to cough. He will be pleased to know that he has not contracted consumption; but he will continue to cough, and as a result may develop chronic pulmonary trouble. A glance at the patient is sufficient to exclude phthisis, bronchitis, emphysema, etc. He is a strong, healthy man, and laughs when questioned as to his appetite, strength, and weight; yet there is in this case some abnormal factor at work which is doing all the mischief, and which must be discovered to be successfully corrected. For this reason no apology is necessary for mentioning pathological conditions, however slight they apparently may be, provided only they are sufficient to produce these grave disturbances. Irritants are always slight in the commencement, but may lead to chronic inflammatory diseases of large dimensions unless treated early, as Riegel[2] says: "The intensity of the paroxysms of cough is in no way immediately dependent upon the extent or intensity of the local alterations, so that we cannot form any definite conclusions from the nature and severity of the cough as to the seat and extent of the pathological alterations."

Uncertain diagnosis renders the prognosis and treatment equally unsatisfactory. It is a great point gained when the physician can account for all symptoms on a pathological basis. From the tip of the nose to the larynx there is ample space for the location of numerous cough-producing factors. Many points of irritation have been discovered, during the past few years, which had never been dreamed of as having any possible connection with a troublesome cough. But now that we know that there is so intimate a relation between parts so distant from one another—as, for example, that asthma may be occasioned by an obstruction in the nasal passages, and that wax in the ear, or a polypus in the vault of the pharynx, may be sufficient to provoke the most harassing cough—we are inclined to investigate thoroughly before admitting ignorance, and classifying the cough in question as a nervous, irritative, reflex, or hysterical one. There are undoubtedly some few coughs which, for want of a better name, but more for want of clearer knowledge, may be so styled; but hysterical coughs are not so frequent as they were five years ago, and they will be less frequent at the end of another five years. Nor do I believe that reflex coughs are very common, provided by that term we mean that the cough-producing irritant is situated in a portion of the body remote from the respiratory tract, as in the so-called "stomachic" cough. Careful investigation will usually reveal an irritant much nearer than the stomach. In uterine coughs, too, although there may be undoubted uterine disease which produces general nervous irritability—yet, granting that a person may possess this predisposition, and that a very slight irritant is enough to produce so marked objective symptoms as a paroxysm of coughing—still an irritant there is, and careful investigation will locate it in the upper air-passages much more frequently than in or about the uterus.

The whole diagnosis is not made, even if a catarrhal laryngitis or bronchitis is discovered; these, like the cough, may be the result of the irritation for which we are searching, and not the irritant itself. We are in the habit of giving the indefinite name of bronchitis to many cases of cough. The lungs are examined, and if a few mucous râles are heard this diagnosis is thought to cover the whole ground. But this, after all, is not going deeply into matters; for mucous râles are present in the chests of thousands of healthy people who have no cough. In our climate, redness of mucous membrane and mucous secretion are commonly found in larynges and bronchial tubes without apparent detriment to the health of the patient, and too much stress must not be placed upon these phenomena as cough-producing factors. Experiments have clearly demonstrated that there are certain localities in the pharynx, larynx, and trachea which are much more sensitive to irritation than the remaining parts—for example, the posterior wall of the junction of the middle and lower pharynx; in the larynx, the interarytenoid fossa, the folds of tissue extending between the epiglottis and the arytenoids, and the glosso-epiglottic ligament. Irritation at any of these points produces a spasmodic cough; while the mucous membrane of the trachea, as a whole, is moderately sensitive, it is particularly so at its bifurcation. All these parts are necessarily intimately associated in sensibility, obtaining, as they do, their sensitive nerve-supply from the same source. No matter how callous any portion of this tract is to irritation, the neighboring tissues will quickly become affected, and coughing will result if the irritation is long continued. Early investigators concluded that cough occurred primarily only in the larynx, but it is now known that cough may be produced by irritation of the terminal filaments of the pharyngeal and superior laryngeal branches of the pneu-

[1] Read by title before the Medical Society of the State of New York, February 3, 1886.

[2] Riegel, Von Ziemssen, vol. iv., p. 277.

mogastric at any point of their distribution—the most sensitive points, however, being those mentioned above.

Perhaps a more appropriate title of the communication would be unrecognized rather than unusual causes of cough, for I believe the ones to be mentioned are not infrequent, but they are certainly apt to be overlooked. For the purpose of intelligent therapeutics, it is as important to understand the exact sources of irritation about the respiratory mucous membrane as to discover the foreign body which is the cause of an ophthalmia. The analogy is a close one; for, as will be seen, it is nearly as unreasonable to prescribe mucilaginous cough-medicines in the one case as to rely on soothing lotions for the eye in which the foreign body is allowed to remain.

I can give the history of a case illustrating this point in a few words. A young woman, nineteen years of age, the picture of health, assured me that she was very well in every particular, except that she suffered from spasms of coughing which were very violent, and which resembled whooping-cough in character, the paroxysms sometimes ending in vomiting. This was the most severe of three similar attacks, which had followed each other at short intervals during eighteen months. She had the inclination to swallow continually, and there was frequently a sensation as though food was lodged in the commencement of the œsophagus. A slight tickling in the larynx was constant; this she could control, but any movement of the throat, as in swallowing, loud talking, deep full inspirations, increased the irritation so much that she was powerless to prevent the cough and

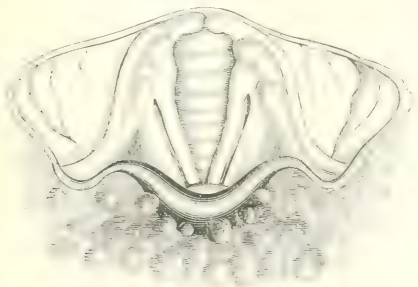

Fig. 1.

glottic spasm. It will be noted that all the symptoms pointed to the pharynx, or the upper part of the larynx, as the locality affected. Her cough was so constant and loud that she greatly annoyed her friends, who thought it could be in a measure controlled, as her general health was so good. A physician, too, had pronounced it a nervous cough, so that family sympathy was not abundant. She had taken expectorants and sedatives, with partial relief for a time. I was greatly interested in searching for the location of the irritant which was causing the cough, as its character demonstrated that it was not a reflex affair (as that term is commonly used), but occasioned by actual lesion. I expected to find, in this particular instance, either an irritable nasal mucous membrane, an elongated uvula, erosions on the posterior wall of the pharynx or tip of the epiglottis, or possibly some laryngeal disturbance. Nothing of this kind was seen, but the following condition was present, as shown by Fig. 1: The papillæ at the base of the tongue were greatly hypertrophied, and the superficial lingual veins were much enlarged. They appeared like a number of large earth-worms. There was no special sensitiveness here, and the probe was rubbed over the whole of the base of the tongue without exciting muscular spasm. The mischief this condition of the tongue was producing was apparent, however, when an attempt to swallow was made, or during sharp, quick inspirations. At such times, the base of the tongue being drawn backward, the large, rough, glossal papillæ folded themselves over the free edge of the epiglottis, so that the latter was bent forward and held securely down; buried beneath them, one-fourth of an inch of the summit of the epiglottis was concealed. The parts remained in this position during ordinary respiration until a strong muscular movement was made, when the epiglottis freed itself and became nearly vertical. It soon became apparent that here was the source of irritation. By careful observation I ascertained that the paroxysms of coughing were not produced when the tongue and epiglottis met.

In fact, at almost every examination the base of the tongue was found overlapping the epiglottis, and this seemed to be the usual position during rest. It was when the epiglottis struggled to throw off the tongue that the patient experienced the irresistible impulse to cough. This appearance truly represented a struggle between the two parts, and the epiglottis was forced to rub its sensitive laryngeal surface across the horny prominences of the tongue. This would seem sufficient occasion for glottic spasm, when it is remembered that the posterior surface of the epiglottis will not tolerate the touch of a probe until it has become educated to such contact. It will be said, in objection to this condition being a frequent cause of cough, that the epiglottis does become accustomed to the touch of the tongue; and this to a certain extent is true. It is well known that the anterior face of the epiglottis is far less sensitive to irritation than its laryngeal surface, exposed as it is to the passage of solid and liquid food. It is a common occurrence to find the base of the tongue lying against the epiglottis, and it is not unusual to see the glossal papillæ extending over its free margin, and touching its laryngeal surface, without creating any disturbance. It is a different matter when, as in this case, the follicles of the tongue overlap the epiglottis to the extent of one-fourth an inch, and rub over so large an area of sensitive surface. Such a condition may, and undoubtedly occasionally does, exist without exciting reflex spasm; but if it occurs in a person having a sensitive mucous membrane, and the irritation is sufficient to provoke coughing, the epiglottis will become more and more irritable, the paroxysms more frequent and severe, until secondarily the pharynx and larynx will become actively congested. In this hyperæsthetic condition everything will act as an irritant and provoke coughing—change in the temperature of the air breathed, dust in the atmosphere, loud talking, fast walking, or even different positions of the body. The patient coughs when he first lies down, and again when he rises. The coughing-fit itself acts as an irritant, and the more violent it is the sooner and more severe will be the following one. It is well to bear in mind the injury done to mucous membranes by the *mechanical violence of coughing*. It is itself a more potent cough-producing factor than most external irritants. Such a condition of the upper respiratory tract will account for spasm of the larynx, laryngismus stridulus of adults, and attacks of suffocation without apparent cause. In such cases great caution should be used in making local applications to the larynx, as alarming glottic spasm may be easily produced.

By further examination, I became convinced that the enlargement of the glandular tissue of the tongue was not wholly at fault in assuming this abnormal position in relation to the epiglottis. The epiglottis must be in some degree peculiar to invite this contact. In all cases that I have seen, the epiglottes have been remarkably thin and supple, and the normal degree of anterior curving of the free margin has been considerably exaggerated. In some instances the epiglottis is rolled up like a scroll. I have seen cases where the tip was bent backward until it touched its own lingual surface. Long and lax aryteno-epiglottidean ligaments, or impaired action of the muscular fibres of the thyro-epiglottideus, may be the cause of such pronounced anterior position. It would seem impossible that an epiglottis of such a shape could become erect or curved backward far enough

to cover the orifice of the larynx during deglutition. The weight of the epiglottis has much to do with its position. In inflammation of this cartilage it is a rule to find it leaning backward toward the œsophagus. It is frequently seen in a horizontal position when inflamed and thickened by phthisical and syphilitic disease; and as the inflammation subsides, it will, little by little, become erect. The following case shows how much the weight of the epiglottis regulates its position. A middle-aged woman came to the office, complaining of cough and slight dyspnœa. A fibroma as large as a small grape was found attached to the posterior surface of the epiglottis near its summit. The epiglottis was otherwise normal. It was bent backward beyond a horizontal plane, and enough to cause the dyspnœa. The growth was removed with the galvano-cautery. That the weight of the tumor was the cause of the depressed position of the epiglottis was apparent, for after its removal the epiglottis gradually became erect, and the dyspnœa ceased. It is, then, in those patients where *the epiglottis has not been attacked by disease*, that we find it tipping forward, and inviting contact with the tongue.

To satisfy ourselves beyond doubt that this condition alone is the cause of cough, we must exclude all other sources of irritation about the ears, nose, pharynx, and larynx. And here I can pay still another compliment to the much-lauded cocaine, by mentioning its great value as a means of diagnosis. Apply a four per cent. solution of cocaine to the nose, pharynx, and larynx, not allowing it to touch the tongue and epiglottis, thus quieting all irritability except at the location. If the cough and tickling continues, it is fair to conclude that we have discovered the cause and source of the cough.

The treatment of these cases is quite satisfactory. The indication is to remove the enlarged papillæ at the base of the tongue, or to diminish their size sufficiently to prevent them overlapping the epiglottis. This is best accomplished by burning them with a galvano-cautery electrode. It is not always necessary to use the laryngoscope when applying the cautery. If the tongue is forcibly depressed, its base can be seen and reached, and frequently the epiglottis, too, can be brought into view. The epiglottis, too, is more easily seen in this class of cases, on account of its high position in the pharynx and its forward curvature. The various caustics may be employed instead of the electric cautery, but great care must be used in limiting their application to the enlarged glossal papillæ. I have found, too, that simple pressure, by means of cotton or sponge attached to a sponge-holder, will produce absorption of this glandular tissue. I have seen most beneficial results from this line of treatment. And in the case reported above, the cough ceased when the hypertrophied tissue of the tongue had been removed.

In another class of cases where, as in those just described, cough is the prominent symptom, the shape and size of the epiglottis will be found to be the cough-producing factors, the base of the tongue being normal. I do not wish to speak of the various well-known varieties of ulcerations which attack the epiglottis in the course of syphilis, phthisis, lupus, carcinoma, etc. There is nothing subtle about these processes; they may be readily seen by looking, and the lesion is usually so well marked as not to escape observation. The epiglottis has always been considered one of the most sensitive portions of the respiratory tract. Its position is one of peculiar exposure; protected somewhat more than the pharynx, it never, like that, becomes thoroughly accustomed, and so eventually insensible, to the irritation of all kinds of solids and liquids, and to the extremes of temperature both in the air breathed and the food eaten. But while it is much more exposed than any other part of the larynx, it retains the fine sensibility necessary to its functions as a sentinel. Erosions along the tip of the epiglottis are spoken of in text-books as one of the results of catarrhal inflammation, and as capable of producing an harassing cough. I am sure they rarely occur in a simple inflammatory process, unless the epiglottis is exposed to friction; and I believe, too, that their presence alone will not account for a constant cough, unless the friction is continuous. In addition, then, to the discovery of an eroded epiglottis, it is wise to ascertain in what manner its epithelial covering became rubbed off. The point I wish to emphasize is this, that where the free margin of the epiglottis is seen reddened and irritable, the merest touch producing a paroxysm of cough, it will usually be found that *the shape of this cartilage* is at fault—it is asymmetrical. A condition spoken of and illustrated by Dr. J. Solis Cohen in his book,[1] but frequently much more exaggerated than there represented. One angle or one-half of the summit is prolonged beyond the level of the other half. The prolongation sometimes ends in a well-curved border, and sometimes extends to a point. The commencement of the asymmetry is congenital, and is not more remarkable than the several other malformations of the epiglottis which commonly occur. No discomfort ensues from this elongation of the epiglottis until it comes in contact with some neighboring tissue, as the prominent papillæ at the base of the tongue, if the epiglottis is bent forward, and I have noted one instance in which the long point of the epiglottis touched the posterior wall of the pharynx during deglutition. The congenital unilateral enlargement of the epiglottis is increased by chronic inflammatory thickening as soon as this condition of contact with other structure becomes permanent. We have now all the conditions favorable for a constant irritative cough—a sensitive epiglottis, so long as to necessarily impinge upon the tongue with every movement of the larynx. A case in point came to the office to-day. The young woman while sitting in a room at some distance from my office coughed constantly and so loud as to be easily heard. I had in this way, before seeing the patient, an opportunity of judging of the character of the cough. It was spasmodic, irritable, and unsatisfactory in that no mucus was expelled from the larynx. The patient was an unmarried woman. Good general health. Family history excellent. The commencement of her cough dated back almost a year. She thought it the result of a cold contracted at that time. The cough, she said, was excited by a tickling, and she placed her hand over the larynx as the location of the irritant. She said, too, that she was "forced to cough until she reached the spot," meaning that the tickling continued until the point where it was felt was forcibly agitated, then there was a brief feeling of relief. Where coughing has for its object the expulsion of an accumulation of mucus, it is natural that the cough should cease so soon as the irritant is removed. This is the legitimate function of coughing, to expel all foreign substances from the upper air-passages and to prevent their entrance into the lungs. And the unusual expiratory efforts are continued until this object is accomplished. But how shall we explain the relief obtained by coughing, and the longer or shorter intervals between the paroxysms, in those cases where, as in the one cited, there is no hypersecretion, but the sensory nerve-fibres are excited by an irritant which remains constantly present, and which no effort can remove or relieve? The act of coughing itself increases the feeling of sensitiveness in the throat until finally the irritation reaches its maximum intensity and then suddenly disappears and the cough ceases. It is probable that the sensory nerves become so shocked by the mechanical violence of the cough that they are for a time insensible to irritation. Their muscular irritability is exhausted, and during the time necessary for recuperation there is no tickling and no cough.

I have already described the lesion and cause of the cough which were found in the case just referred to, and they are well shown in Fig. 2. An epiglottis elongated at its left superior margin, one-third of an inch beyond that of the remainder of the free border—this prolonga-

[1] [illegible]

tion ending in a point. The epiglottis was bent sharply forward over the base of the tongue, and rested upon, or was buried beneath, some of its papillæ. The point of the epiglottis was in a condition of chronic inflammation, red and thickened, and the mucous membrane rough and granular. The unusual length of the epiglottis was evidently steadily increasing under the constant friction against the horny tissue of the tongue. It required but a moment to prove that here was the seat of the trouble, for when the long point of the epiglottis was touched with a probe the patient recognized the location as identical with that of the seat of chronic irritation, and the same cough was produced. Most positive evidence, however, was obtained by the action of cocaine, and this is a use of this drug which I have not heard spoken of. It was employed in this manner: It was applied only to the elongation of the epiglottis by means of a small pledget of cotton wrapped about a probe. This effectually excluded from consideration an irritation arising from this point, and as the entire feeling of tickling was gone, it was just to conclude that this was the entire irritant. The value of cocaine, then, as a means of diagnosis by exclusion, is another point to be recorded in its favor. This drug is particularly useful, too, in the treatment of these patients. And in those cases where there is but slight elongation of the epiglottis, cocaine may be all that is required. Its effect on the epiglottis is similar to that on other mucous surfaces: it reduces its size by con-

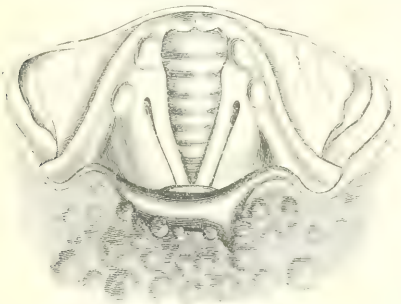

Fig. 2.

tracting the enlarged capillaries and forcing out the blood. The decrease in size is in proportion with the degree of congestion which exists. In the same way cocaine levels the hypertrophied tissue of the base of the tongue. By applying the drug several times daily some permanent reduction in size may be gained by obliteration of capillaries. If the length of the epiglottis is too great to be removed in this manner, more radical measures must be employed, and the galvano-cautery is the best instrument.

With the platinum point the hypertrophied tissue of the epiglottis can be removed and its elongated free margin be made symmetrical.

The "unusual causes of coughing," then, are two: First, *hypertrophied, glassy papillæ, overlapping an epiglottis, which is bent far forward, but otherwise normal;* and second, *a congenitally assymmetrical epiglottis, which has been made still longer by inflammation, caused by constant friction with the tongue.* Abnormal conditions of the tongue and ulcerations of the epiglottis are mentioned in text-books as sources of irritation and causes of cough, but this relation between the tongue and the epiglottis has not been specially recognized as a strong cough-producing factor. I believe it is very frequently so. I consider the recognition of this lesion to be of great importance to the physician; for it explains the etiology of many coughs the causes of which have not hitherto been accurately determined. Since my attention was first called to this lesion, I have seen many cases in which it existed, and in which it could be demonstrated beyond a doubt that it was the sole cause of cough.

A SUCCESSFUL CASE OF LAPAROTOMY FOR PERITYPHLITIC ABSCESS.[1]

By JOHN HOMANS, M.D.,

INSTRUCTOR IN HARVARD UNIVERSITY IN THE DIAGNOSIS AND TREATMENT OF OVARIAN TUMORS, VISITING SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL.

In The Medical Record of March 6, 1886, appeared an excellent article, by Dr. William T. Bull, on the subject of early interference in cases of perityphlitic abscess. The case which I have lately operated upon is one of earlier interference than that of Dr. Bull, if we date from the first symptom of pain, but a later one by about a day, if we date from the time the patient took to his bed. At the same time, as my patient was a boy aged eleven, he may not have remembered his symptoms and the duration and locality of his pain as well as an adult would have done. Dr. J. S. Greene, of Dorchester, was called to see the boy on Saturday evening, January 9, 1886. I operated on Monday, January 11th. Laparotomy was done without previous aspiration over the most tender point, which was one and a half inch above, and a little posterior to, the right antero-superior spine of the ilium. Nothing like pointing existed. You will notice that this laparotomy was done within forty-eight hours of the doctor's first visit, and when the patient had been in bed less than four days. The very first symptom of pain and uneasiness had appeared within five days. All the cases of acute perityphlitis that I had seen demonstrated by dissection during the last twenty-five years had been at autopsies, and death had usually taken place about a week after the first symptom had appeared. Dr. Greene and I decided not to wait for the autopsy.

Dr. Bull's patient had a steady, dull pain in the inguinal region for ten days before he took to his bed, so that if we date from the period of decubitus Dr. Bull's operation is the earlier; if from the first symptom of disturbance, mine is the earlier. But this is a question of little importance. The point on which Dr. Bull and myself would agree in urging upon the profession is that in most of these cases an operation, to be of any service, must be done early, *very early*. I could not find a dull place in which to pass a needle, and so I thought it more intelligent to dissect down through the locality of greatest tenderness. I think the wisdom of this was shown by the operation, for I came down first on perfectly healthy bowel, and it was only by separating and poking the loops of intestine apart that I was able to open the abscess. If I had thrust in the needle at the point where I made the incision, I should have perforated the bowel at least four times before I could have struck the collection of pus, and I might have missed it entirely. If I had aspirated just below the kidney, in the right loin, I should have hit the right spot, and perhaps this would have been better surgery in point of drainage, and as not opening the peritoneum. However, as the patient was cured, it may be that my incision was as well placed as one further behind would have been. I will give you the history of the case that you may understand it more clearly. The patient was a boy, eleven years of age, never robust. On Wednesday, January 6th, he had some pain in the bowels; on Thursday he had more pain, but he still kept about. On Friday his pain became worse, and he called attention to it and remained in bed. On this day he had a dejection. Dr. Greene saw him on Saturday evening the 9th, and found him in bed with a temperature of 102.4°, and a pulse of 120. His tongue was coated white. There was dulness on percussion over the right iliac and lumbar regions, with the centre of tenderness about one and a half inch above the anterior spine of the ilium. There was no swelling. The other parts of the abdomen were somewhat compressible. Morphia was given, and a poultice applied.

[1] Read before the Surgical Section of the Suffolk District Medical Society, April 13, 1886.

On Monday, the 11th, the pulse was more frequent and the abdomen less yielding; small quantities of liquid nourishment had been taken and retained. Dr. Greene called me to see the patient in the afternoon, and I performed laparotomy at the point above mentioned. No spray was used. An incision about two and a half inches long was made, and the peritoneum opened; the healthy bowel presented itself. On passing my finger below and behind the presenting loops I felt coils of intestine filled with fecal masses, or perhaps also enlarged glands. The loops of intestine were adherent to each other by a recent plastic process, but by poking about with my finger and separating them I opened an abscess, and about two ounces or more of foul-smelling ("rotten egg") pus welled up out of the wound. So far as we could, we prevented the pus from running in among the coils of intestine, and after emptying the abscess as well as possible, a double drainage-tube was passed into its cavity and the incision closed around the projecting ends of the india-rubber tube. The boy did not sit up out of bed till February 3d, about three weeks after the operation. His temperature varied from 99° to 102.9°, and he required opiates for four days. His bowels moved on January 15th. The wound discharged freely for a fortnight, and united by granulation. He is now well, hearty, strong, and is gaining flesh. The credit of the cure belongs more to Dr. Greene than to me, as I was only his instrument in the case. There is not the least tendency to hernia, but I have had an elastic abdominal supporter fitted, as I always do after a recovery from laparotomy, for whatever purpose done.

(Dr. Homans now showed the patient undressed, and pointed out the site of the incision and the cicatrix, which was firm and solid. The boy looked healthy and strong, and had gained many pounds in weight. He is perfectly robust and active.)

POINTS IN THE THERAPEUTICS OF DISEASES OF THE JOINTS.

By A. B. JUDSON, M.D.,

NEW YORK.

It is sometimes said that the treatment of joint diseases is enveloped in obscurity, and that the methods in use are various and conflicting. As an attempt to clear up the therapeutical atmosphere, I would like to make two or three points, as our legal brethren would say.

In the first place, I think we fail to recognize and acknowledge that articular osteitis is, from the nature of the case, an affection of long duration, and one in which absolute restoration to perfect symmetry and complete function is very decidedly the exception and not the rule. In these days of brilliant and painless operations and marvellous discoveries in physics we resent being limited to simply reducing deformity and placing the part and system in a favorable position for the slow processes of natural repair. Until a perfect cure has been found, however, and tested by time, it is better not to disappoint our patients, but to give them the assurance that they will receive at our hands all that the present state of science can grant.

In the second place, I think obscurity has been caused by the mistaken precedence which has been unwittingly given to mechanics over pathology. The machinery of the joint being out of order, and certain muscles abnormally contracted, we have concluded that it is a question of dynamics, and that the pressure incident to muscular action is the cause of the destruction of cartilage and bone. Instead of prudently stopping to verify this conclusion by the examination of morbid specimens, which prove that muscular action plays but an insignificant part, we seek a mechanical remedy for what appears to be a mechanical lesion, and invent an apparatus for counteracting the muscles. And when the apparatus is adjusted and the symptoms abate we congratulate ourselves and imagine that the relief experienced is a proof that the muscles were causing all the mischief, failing to see that we cannot directly oppose the muscular action at all, and that, without knowing it, we have fortunately been applying fixation, which is a constant accompaniment of traction, and which a timely resort to pathology would have told us was the very thing which the inflamed joint needed. I have none of my fellow-workers in view (we have all been followers of Dr. Henry G. Davis), but have simply tried to show how pathology and mechanics have failed to walk hand in hand, as they should have done, in the treatment of joint diseases. The therapeutical precepts suggested above have been expressed in detail in former papers,[1] and sustained by reasons which seem to me conclusive.

The third point I wish to make is, that anchylosis has not been given its proper value in the formulæ of this therapeutical problem. When long-continued inflammation has rioted in the tissues of a joint, deforming the articular surfaces and locking them up in organized lymph and shortened ligaments, we have anchylosis, the ultimate degree of which will depend, in my opinion, on the promptness and success of our efforts to arrest the inflammation. And I think that we are wrong when we fear adding to the amount of ultimate anchylosis by early and thorough fixation of the joint. To me it seems reasonable that such a course will diminish the resulting anchylosis by subduing the inflammation and preventing an excess of its products. The statement has been made, and I believe can be sustained by records, that fixation of a healthy joint, no matter for how long a period, is powerless to produce anchylosis. It causes a temporary arrest or impairment of motion, such as can be overcome by habitual effort on the part of the patient, a disability very different from the anchylosis following inflammatory disease, which is, with rare exceptions, permanent. If this view be correct, then fixation is to be applied as early in the case as possible, and with uncompromising persistence, in the belief that, so far as the joint is a healthy one, fixation is absolutely harmless, and that so far as the joint is diseased, fixation will, by subduing the inflammation, increase ultimate mobility.

There are, of course, other sources of obscurity, and this will be the case until we attain omniscience. I cannot but think, however, that the three points which I have tried to make dissipate some of the difficulties in the way of the unanimous recognition of correct methods.

HEMIGLOSSITIS.—Dr. R. Delaine reports (*Wiener Medizinische Wochenschrift*, No. 7, 1886) a case of a child, aged six months, whose tongue became rapidly swollen, so that it projected from the half-opened mouth. Examination showed that the swelling was confined chiefly to the right side, the surface of which was covered with yellowish-white vesicles, from the size of a millet-seed to that of a pin-head, arranged in groups. Similar vesicles were visible also on the inner and outer sides of the right cheek. On the fourth day the swelling subsided as rapidly as it had come, and the vesicles dried up and disappeared. From the similarity in symptoms and course of the disease to those of herpes zoster, the writer regarded it as a form of this affection. Two similar cases, occurring in adults, are reported by Dr. P. Güterbock (*Centralblatt für Chirurgie*, No. 7, 1886). In both of these cases, also, the affection was confined to the right side of the tongue. In these and other cases the seat of the disease corresponded almost exactly to the area of distribution of filaments of the trigeminal nerve, and in some reported instances there seemed also to be a participation of the chorda tympani in the disturbance. The glosso-pharyngeal and the hypoglossal nerves, on the other hand, seemed in none of the cases to have any etiological relation to the affection.

Clinical Department.

THE MODE OF PERFORMING COLOTOMY—WITH A CASE.

Dr. William H. Sherwood, of Painesville, O., writes: "In performing colotomy the colon has been approached in several different ways. Litter, in 1710, was the first, perhaps, to suggest this operation, and recommended reaching the sigmoid flexure through the left iliac region; but it was not until about sixty-five years afterward that his suggestions were carried out by Pillore, who cut into the cæcum through the right iliac region, and stretched the bowel to the parietes. This operation was undertaken in consequence of malignant disease of the rectum.

"About a quarter of a century later, in 1797, Fine operated through to the transverse colon in the umbilical region for cancer of the rectum. A short time previous to this, Callisen advised the left lumbar region as the best route, and the sigmoid flexure as the most proper portion of the intestine to be opened. When the obstruction is situated in the rectum or sigmoid flexure, undoubtedly the operation is most successful. In my judgment, left lumbar colotomy is much preferable to any other, and there is less danger of wounding the peritoneum. The incision as recommended by Amussat, and more recently modified by Bryant, is the best, as we more effectually avoid the inferior lumbar arteries, and on account of the gaping nature of the wound we can much better distinguish the parts. If an immediate incision into the bowel be demanded after the dissection down to the bowel, the method recommended by Agnew is the safest and best that has come under my observation. But this should always, if possible, be avoided. The intestine should be held *in situ* for four or five days, until adhesions have taken place. Bryant, Davies Colley, Lucas, and others have been in the habit of covering the blades of their dissecting forceps with French rubber tubing, and including a small portion of the bowel between them, with the forceps situated crosswise the wound. It occurred to me that a two-pronged, hard-rubber, ladies' hairpin, with the prongs covered with French rubber and the inner surface lined with rubber adhesive plaster, would be just as effectual, and much lighter; and I am happy to say it served every purpose. The prongs, concave in their long dimension, admirably adapt themselves to the transverse surface of the lumbar region. Davies Colley had an instrument constructed that rested on each side of the wound, and fixed the gut in position by a screw with a universal end. But I think the hair-pin equally as good, much lighter, less cumbersome, less expensive, and not as likely to get displaced.

"Through the kindness of my friend, Dr. E. B. Root, of this city, I was called to see Mrs. F. S——, a lady aged fifty-seven, married, who had never borne children. She was much emaciated; pulse, 120, and the countenance denoting great suffering. Upon endeavoring to pass the finger up the rectum there seemed to be a very small and tortuous channel; in fact, it was impossible to explore it with any degree of accuracy. The vagina also was involved to that extent that hardly a semblance of an os or cervix could be distinguished, and during the imperfect, scanty, and painful evacuations a small amount of fæces could be observed escaping from the vagina. She did not suffer from tympanitis or emesis as much as usual in these cases, on account of the judicious use of the bougie in the hands of her family physician. As nearly as could be ascertained, the disease had commenced about eight months previously.

"Colotomy was advised as a palliative measure, and January 1, 1886, after she was thoroughly anæsthetized and placed in the proper position, assisted by Dr. E. B. Root and others, I commenced Bryant's incision on the left side, one inch above and one inch behind the anterior superior spinous process of the ilium, carrying it obliquely to the inferior rib, and within one inch and three-quarters of the spine. After carefully dissecting through the obliquus externus, internus, and transversalis facies the border of the quadratus came into view; after pushing my finger through the little bed of cellular tissue, the left kidney was found displaced downward, and somewhat enlarged, but not otherwise diseased. The kidney was pushed to one side, and after considerable difficulty in manipulating I succeeded in hooking my index-finger under the colon and bringing it into the wound, where it was securely fixed with the above-described clamp. The wound was dressed with carbolized oil, and its cutaneous portion, up to the intestine, nicely closed with silver suture. Then a thick compress of carbolized jute was placed over the wound, and a broad bandage was passed around the loins, securing the dressing.

January 2d.—Reaction had come on nicely, no elevation of temperature; pulse, 100.

"January 3d.—Very comfortable, very slight elevation of temperature; pulse, 90.

"January 4th.—No alteration; expressed a desire for food, was allowed beef-tea.

"January 5th.—No elevation of temperature. Examined the wound; adhesion had taken place perfectly. We removed the hair-pin and made an incision into the intestine three-fourths of an inch long; gas escaped quite freely.

"January 6th.—Is very comfortable, free from fever; pulse, 84; is hungry, and has had a slight movement through the new opening. Nothing new has occurred up to this—January 23d—in her case; the wound has entirely healed; the artificial anus is thoroughly established."

Progress of Medical Science.

Transplantation of Tendons.—Dr. Assaki states that it is possible to replace a portion of a tendon an inch or more in length by a similar piece taken from another animal. When the operation is performed under antiseptic precautions union takes place in about a week, without any impairment of function of the tendon, which glides in its sheath normally, unrestricted by adhesions. He has made successful transplantations, not only from one animal to another of the same species, but also from dogs to rabbits, and the reverse, and even from birds to mammals. Subsequent examination of the animals operated upon showed complete union of the sutured tendons, the only trace of the operation being an increased vascularization of the tendon sheath. The author argues that the operation ought to be equally successful in the human subject. In his experiments the transplanted portions were united to the divided tendons by catgut sutures, and strict antisepsis was maintained.—*St. Petersburger Medicinische Wochenschrift*, No. 7, 1886.

The Recurrence of Stone in the Bladder.—Mr. Reginald Harrison reports, in the *Liverpool Medico-Chirurgical Journal* for January, 1886, the case of a man, sixty-two years of age, upon whom he performed lithotomy twice at an interval of less than fourteen months. The first operation was very thoroughly performed, and it was thought that every portion of calculus had been removed, but the wound in the bladder never completely closed, and the writer believed that a sacculated stone had escaped detection. This view was strengthened by the appearance of the calculus removed at the second operation, as it was seen to consist of two layers, a nucleus and an outer friable phosphatic crust evidently of recent formation. Mr. Harrison regards the case as instructive in showing how impossible it is to be absolutely sure that every bit of calculus has been removed, and consequently how unjust would be the criticism passed, more particularly in the case of a young surgeon, if in a similar instance the patient should die and an encysted stone be found at the autopsy. In discussing the causes

favoring the reproduction of stone he says that an enlarged prostate is a very prominent one, and it seems to bring this about in two ways. In the first place, persons who may have been in the habit of voiding renal calculi for a considerable number of years find, after a certain age has been reached, that they no longer do so, and continued vesical irritation follows an attack of renal colic. The explanation lies in the fact that their prostates have commenced to enlarge, and thus stones which previously escaped spontaneously are practically trapped. In the second place, the large prostate, by permanently altering the shape of the outlet from the bladder, and thus causing urine to be constantly retained, engenders a state of chronic cystitis and excessive excretion of mucus, which are the invariable preliminaries to the formation of phosphatic stones. Mr. Williams has found, from the statistics of operations for stone in the bladder in the Norfolk and Norwich Hospital, during a period of ninety-seven years, that relapses occur in the proportion of one to thirty-six; but in these statistics both males and females are included, whereas, relapses occurred only in males, so that the proportion is really somewhat greater than these figures would indicate. Mr. Harrison prefers lithotomy in cases associated with enlarged prostate, with a view of improving the condition of the prostatic urethra by a free section, according to the method described by him at the International Congress of Copenhagen.

Araroba in the Treatment of Psoriasis.—Dr. Borogoditsky has used with success an ointment composed of one part each of araroba and acetic acid, in thirty parts of lard. The ointment is to be rubbed upon the affected parts two or three times a day. The author speaks highly of the good results obtained by him by this method.—*Centralblatt für Chirurgie*, No. 7, 1886.

Treatment of Sweating of the Feet.—Dr. Hebert gives, in the *Journal de Médecine et de Chirurgie Pratiques*, No. 2, 1886, the details of a method first suggested by Dr. Legoux, which he has found most efficacious for the relief of sweating of the feet. For three days the feet are bathed, for half an hour at a time, morning and evening, in tar-water. At the end of the third day the pediluvia are omitted, and the soles of the feet are painted once a day with perchloride of iron. After four days more the epidermis of the soles is found to be dry and hard. Dr. Hebert succeeded in obtaining a complete cure by this simple means.

Congenital Dislocation of the Patella.—Dr. Besselhagen has met with two cases of this rare condition, occurring in brothers, one of whom had a bilateral luxation, and the other a unilateral dislocation of the patella, with congenital dislocation of the hip. He has succeeded in obtaining the records of fourteen other cases, from a study of which he is led to divide the affection into three classes: 1, Complete luxations, in which the patella lies to the outer side when the leg is extended, but returns to its normal position on flexion of the knee; 2, intermittent luxations, occurring only during flexion, the patella resting on the outer condyle of the femur; 3, permanent luxations, in which the patella rests constantly on the external condyle in whatever position the limb may be, though the degree of dislocation may be increased by flexion. It was noted with some surprise that there was no in-deviation of the knee in any of these cases, but it was probably due to the fact that the internal condyle of the femur was always found to be smaller than normal, and also that the lower end of the shaft of this bone had an inward twist. In three of the cases studied there was an upward dislocation of the patella.—*La Riforma Medica*, No. 30, 1886.

Tubercular Meningitis Following Lupus.—Dr. Doutrelepont reports the case of a young man who came under treatment for lupus. He had cervical abscesses, and was pale and thin, but nothing abnormal could be discovered on physical examination of the chest. He was seized some time later with symptoms of meningitis, and died. At the autopsy miliary granulations were found in the pia mater at the base of the brain, and at the level of the fissure of Sylvius. Examination of a drop of blood drawn a few days before death showed three tubercle bacilli, and the same micro-organisms were found in the blood of the jugular vein after death.—*Rivista Internazionale di Medicina e Chirurgia*, No. 1, 1886.

Nux Vomica in the Treatment of Prolapse of the Rectum.—Dr. Schwartz has employed with success nux vomica for the cure of prolapse of the rectum, not only in children but also in adults, and in chronic as well as in recent cases of the affection. He dissolves a grain to a grain and a half in an ounce of distilled water, giving from six to ten drops to adults, five drops to a child ten years old, and two or three drops to an infant, every four hours. The author asserts that the prolapse disappears under this treatment in the course of twenty-four hours. In order to prevent a relapse he gives the remedy twice a day for a week. When the prolapse is of long standing and does not respond promptly to the action of the nux vomica he adds some extract of rhatany, which, by its astringency, prevents the increased action of the bowels sometimes caused by the nux vomica.—*Gaceta Médica Catalana*, February 15, 1886.

The Treatment of Ring-worm.—Dr. Saerlis recommends oil of turpentine for the cure of ring-worm of the scalp (*Medicina Contemporanea*). The hair should be closely cut over the affected part, and for a short distance around, and then turpentine is to be liberally applied, and rubbed in well with the finger. This is allowed to remain for about five minutes, and is then washed off with carbolic soap, and afterward with hot water, and the patch is then painted with dilute tincture of iodine, or with a two-per-cent. solution of iodine in turpentine. The application is to be made once or twice a day, and is not painful, though it causes a slight smarting. The writer asserts that he has cured, in ten days, by this method, cases of ringworm that have resisted all other modes of treatment.

Hemostatic Powder.—Professor Bonafoux, at a recent meeting of the Academy of Medicine, at Paris, read a paper upon a powder which possesses great hemostatic powers, and is capable, it is said, of arresting the bleeding of large arteries, so that it will prove serviceable in important surgical operations. The powder is prepared by mixing equal parts of colophony, carbon, and gum arabic.—*Medical and Surgical Reporter*, March 13, 1886.

Anæsthesia of the Hand.—At a meeting of the Midland Medical Society, held on February 3d, Dr. Suckling showed a man who had been under his care suffering from complete anæsthesia of the left hand (*The Lancet*, March 13, 1886). Ten months previously, in lifting an eighteen-gallon can of milk with a fellow-porter, his assistant dropped the can, and the patient suffered a severe strain of the arm; anæsthesia and paresis of the hand immediately followed. There was no trophic or electrical change, and the only symptom that might have indicated actual injury to the roots of the brachial plexus was a slight dilatation of the left pupil, which might have been due to irritation of the root of the first dorsal nerve. Dr. Suckling concluded that the case was one of functional hyperæsthesia, and probably due to hypochondriasis, the man seeming depressed. The functional nature of the affection was proved by his rapid recovery after faradization, and by the fact that if, when blindfolded, a mark was made some distance below the line where he said he could feel, when the bandage was taken off he always felt down to this mark, so that a daily diminution of the area of anæsthesia was produced by deceiving him in this manner.

THE MEDICAL RECORD:

SYPHILIS AND RACHITIS.

A CURIOUS example of a theory founded upon pure reasoning without the support of facts behind it—indeed, in the face of facts against it—was Parrot's assumption of the syphilitic origin of rickets. It will be remembered that, in the paper which he presented at the seventh International Medical Congress, held in London in 1881, he asserted that hereditary syphilis was the sole cause of rachitis, and that the latter was simply the most advanced stage of the osseous changes occurring in inherited syphilis.

Professor Parrot's argument, upon which his theory was based, is well summed up in the *Progrès Médical* of January 23, 1886. A careful examination of a number of anatomical preparations taken from the museum of the Hospice des Enfants-Assistés, led him to the following conclusions: 1. In still-born fœtuses, in abortions, and in newly born children dying from hereditary syphilis there is a production of new layers of bone-like tissue, true osteophytes, at the periphery of the long and flat bones; at the same time, in many cases, the cartilage in the neighborhood of the epiphyses is infiltrated with calcareous salts. 2. In a second type, certain portions of the bone are replaced by a soft, succulent, jelly-like tissue (gelatiniform atrophy), sometimes causing syphilitic pseudo-paralysis. 3. In a third type is found the spongoid tissue described by Jules Guérin. According to Parrot, the osteophytic change was the specific and characteristic lesion, and the others were merely degrees of the first, and did not differ from it in their essence or origin. If, therefore, the cause of one could be discovered, that of the others would be the same. The first two changes above described were to be found, he maintained, only in children presenting on the skin or in some of the viscera incontestable marks of hereditary syphilis, and he therefore urged that the third lesion, the spongoid tissue, was also dependent upon the same disease. Up to the day of his death Parrot maintained this theory, in spite of the strongest evidence to the contrary based upon clinical facts and upon the results of treatment.

It would seem to be a work of supererogation at this day to bring forward any new facts in opposition to these views, but yet, so well did Parrot and his followers argue their case, that there are still some who regard with suspicion the parents of every rachitic child, and we think, for their sake, and for the sake of the innocent parents, it may not be out of place to reproduce two striking cases published in *La France Médicale* of January 7, and February 9, 1886. The first case was that of Dr. L. Gaillard, who was called to attend a primipara in childbirth. Everything passed off well, and the case was lost sight of. Eight months later he was called to see the child, and found him suffering from well-marked rickets. On inquiry it was learned that the infant had been nursed for but a brief period, and was fed early on soups and bread-pap; he had also been poorly cared for, and was seldom taken out into the open air. A sufficient cause for the rachitis was therefore existent in the hygienic and dietetic conditions, and this was emphasized upon the birth of the second boy, who was well cared for and properly nourished, and who showed not the faintest signs of the disease. Over two years after the birth of the first child, and nearly a year after that of the second, Dr. Gaillard was consulted by the father, who had an indurated chancre on the prepuce, and soon after suffered from roseola, mucous patches, and cervical adenopathy. It was thus demonstrated that the father could not have been syphilitic at the time of the conception or birth of his children. The mother, had she been unfaithful to her husband, and had she had a syphilitic child by another man, ought (according to the general opinion of syphilographers), even though she manifested no specific symptoms at the time, to have acquired an immunity from the disease. But soon after her husband's misfortune she too presented all the symptoms of secondary syphilis.

This case demonstrates that a rachitic child may be born of non-syphilitic parents, and the second case, related by M. C. Giraudeau, shows that a non-syphilitic child may be born of rachitic parents, who themselves may acquire syphilis at a later period. Both the man and his wife presented numerous rachitic deformities of the bony framework. The first child was born dead, forceps being necessary to effect its delivery. At the second pregnancy premature labor was induced at the eighth month. This child lived, and was eight years old when first seen by Dr. Giraudeau. He then had impetigo, was suffering from suppurating cervical glands, and presented many well-marked scrofulous symptoms, but was free from any signs of rickets. Some months later the mother presented herself with all the evidences of secondary syphilis, and the father confessed to having had a chancre six months previously, which was followed by roseola and mucous patches. Some of the latter were still present at the labial commissures, and there was an indurated cicatrix on the penis. If these people, having had rickets, were the subjects of hereditary syphilis, it is difficult to believe that they could have acquired the disease in later life.

M. Giraudeau refers to other cases of like nature, but it is useless to relate them here, as these two seem to be all-sufficient to demonstrate to a certainty that rachitis is not solely and invariably dependent upon hereditary syphilis. It does not follow, however, that the two affections may not exist in the same individual, and react one upon the other to intensify the osseous lesions. It may well be, as Mr. Hutchinson remarked in one of his Lettsomian lectures, that the existence of the rachitic state in an infant who has also an inherited taint of syphilis may

give a decided tendency to bone-disease, and more especially to affections near the epiphyses. The local pathological product may also be a mixed one, and partake of the combined influence of the two causes. There is, indeed, no reason why the two causes should not mix. But this is very far from admitting that the two processes are identical, or from imputing syphilis to one or both parents of a rachitic child.

A WARNING TO THE CARELESS.

Cleanliness is said to be next to godliness, but we are not sure that this order might not be reversed, in many cases at least, with the result of increasing the sum total of physical comfort and health. One immense advantage of Listerism, which even the most obstinate opponents of the method will not venture to deny, is that it insures absolute surgical cleanliness, and many, indeed, believe that herein consists its sole merit. But, be that as it may, the medical profession, or rather the community at large, has cause to congratulate itself that it is living under the new dispensation of the gospel of cleanliness, and not dying from poison unconsciously administered by a careless and dirty medical attendant.

A case occurring in the service of M. Lancereaux, at the Hôpital de la Pitié, and reported by M. Bezançon in *L'Union Médicale* of March 23, 1886, contains so evident a moral that we think it deserves prominent mention. The patient was a robust man, fifty-three years of age, who came under treatment for acne syphilitica. He denied ever having had an impure connection; there were no evidences of a primary lesion about the genital organs, and the inguinal glands were normal. In the neck, however, and about the inferior maxilla, were several enlarged and indurated glands; these were confined to the right side, the left side being entirely free. Upon inquiry as to the possible means of infection, it was ascertained that the man was deaf in the right ear, and that catheterization of the Eustachian tube upon this side had been performed several times. The second operation, practised some six weeks after the first, had been followed by a sanious and bloody discharge, which, it seems probable, came from the then fully developed primary sore. Allowing twelve weeks from the inoculation to the appearance of the cutaneous lesion, the correspondence in dates would be perfect, and would point to the first catheterization as the period at which the disease was communicated.

Other cases of like nature have been reported. During the years 1864 and 1865 there was quite an epidemic of syphilis in Paris, due to the negligence of a physician who, among other specialties, had that of communicating the disease through the nasal passages. And we doubt not that many an unfortunate has acquired syphilis from catheterization of the urethra, although, as there was a sufficient cause already existing, the instrumentality of the medical attendant may never have been suspected.

A physician or a surgeon cannot be too careful in cleansing his instruments—especially those employed in the various mucous cavities for the purposes of diagnosis—every time that they have been used. They ought always to be washed in a sublimate or carbolic solution, and, if possible, passed through a flame. The practice of putting a clinical thermometer under a patient's tongue, and then returning it to its cloth-lined case after a hasty wipe (as is often done), is particularly deserving of condemnation.

CARELESS INDORSEMENTS BY PHYSICIANS.

We publish below the letter of a prominent physician of this city, and trust that our readers will take note of the warning which he gives.

The petition referred to may be a very good one, but, on the other hand, there is unfortunately some reason to suppose that it may contain some job. Aside from any other consideration, the language of the petition is so extraordinarily ungrammatical, and in parts meaningless, that we cannot believe that it has been carefully read by the distinguished gentlemen who have so far signed it.

Our correspondent says: "I have just been asked to sign the most innocent-looking document—an appeal to the Health Officer to rigidly disinfect all rags, etc., coming into this port. It is already signed by probably fifty of our leading men, who in signing it doubtlessly thought that they were performing a praiseworthy act of good citizenship in giving their approval to this appeal. Now, what are the probabilities in this piece of business? Is it not more than likely that as time goes on it will be discovered that the good name and great influence of our profession have been made instrumental in promoting, not the welfare of the community at large, but the invested interests of some great monopoly?

"Perhaps I am all wrong in my fears, but when I recollect how, on more than one occasion, the good name of the profession has been dragged through the mud through the good-natured signing of just such an innocent-looking appeal as this, by the very best physicians of our city, I feel like begging you, in your editorial capacity, either to investigate and demonstrate the groundless character of my fears, or to sound a timely note of warning."

FURTHER OBSERVATIONS WITH REGARD TO INTRA-PULMONARY INJECTIONS.

Dr. Shingleton Smith has made intra-pulmonary injections forty-two times in five cases. The ethereal solution of iodoform, in solutions of one grain to five minims, was used for the purpose. No harm was done by any of the injections. The positive results were, in a case of lung gangrene there was diminution of fetor and some temporary alleviation of symptoms. In one case of chronic tubercular pleurisy there was very marked improvement; in two other cases there was a slight improvement. Dr. Smith injected the fluid into cavities in the lungs, not into consolidated tissue.

At a meeting of the Clinical Society of the Post-Graduate School, February 7, 1885, Dr. M. Putnam-Jacobi reported one case in which injections of iodine had been used; Dr. Wendell C. Phillips reported two cases, and Dr. A. H. Smith reported one case. In all instances dilute solutions of iodine were used. No bad symptoms followed, while in one of Dr. Phillips' cases, and in the case of Dr. Smith, some improvement was apparent. In this latter case the injections were given every three hours for two weeks, during which time the patient gained three pounds and a quarter. From five to ten minims of

a solution containing one part of Lugol's solution to five of water were employed.

Dr. Gouguenheim has recently described his experience with parenchymatous injections of bichloride of mercury in phthisis. These he made both into the consolidated lung (in solutions of 1 to 2,000) as suggested by B. Robinson, and into cavities (in solutions of 1 to 1,000 and 1 to 500). About fifteen drops were used at a time.

Dr. Gouguenheim employed this method in thirty-three cases, in twenty-one of which there was much improvement. Cough and transitory hæmoptysis occasionally occurred, and no pain was caused. The needle used was a long one, and the injection was made in the first or second intercostal space. Arsenic, quinine, and cod-liver oil were given during the course of treatment.

A novel method of employing intra-pulmonary injections has been devised by Dr. Max Reichert, of Rostock, and an account of it is given in *The Medical and Surgical Reporter* of March 6th. This method consists in injecting medicated liquids directly through the larynx into the trachea and bronchi. The method was tried six years ago for chronic bronchitis, but Reichert introduces and systematizes its use in phthisis. Some experiments on animals led him to believe that the injections are distributed throughout the lungs. The substances used were solutions of the volatile oils, salicylic acid, and chloride of zinc. The best results were from eucalyptus oil and salicylic acid. A description of the technique is given in *Archiv für klinische Medizin*, vol. 37, H. 5. Reichert claims to have employed his injections in sixty cases, always with favorable results.

DIPHTHERIA NOT A SEWER-GAS DISEASE.

Dr. Erwin F. Smith, in an elaborate paper on the "Influence of Sewerage and Water-supply on the Death-rate in Cities" (Report of Michigan State Board of Health, 1885), claims to establish the three following propositions:

1. Typhoid fever and cholera decrease in proportion as a city is well sewered.

2. There is no direct relation between diphtheria and sewers.

3. The general death-rate falls after the sewering of a city, and, other things being equal, never again reaches the maximum of its anti-sewered condition.

4. The cost of sanitation is incomparably less than that in sickness and death resulting from neglect of sanitation.

Dr. Smith's statements with regard to diphtheria and sewerage are:

"1. Diphtheria is as frequent in the country as in the city, *i.e.*, in non-sewered as in sewered districts.

"2. Diphtheria has been more frequent and fatal in certain rural districts than in any city whatsoever.

"3. Diphtheria is not more frequent or fatal in sewered cities than in unsewered ones.

"4. Of two given cities, equally well- or ill-sewered, diphtheria, during a long series of years, may be widely prevalent in the one and rare in the other.

"5. Certain sewered cities have never suffered seriously from diphtheria, while others have been afflicted very much worse in recent years (*i.e.*, since the houses have been protected from sewer-air), than formerly, when with the same sewers, but much less perfect plumbing, flushing, and ventilation, the sewer-air found its way into a majority of the houses.

"6. When an epidemic of diphtheria appears in a city the sewered and unsewered portions generally suffer alike.

"7. No relation of interdependence can be traced between diphtheria and the sanitary state of a city, such, for example, as enables us to predict with almost absolute certainty the typhoid fever mortality of a city from a knowledge of its sanitary condition, or conversely, the sanitary condition from its typhoid mortality.

"8. The annual mortality from diphtheria fluctuates greatly, and this, too, in cities where the sanitary conditions are very nearly constant.

"9. Diphtheria is a disease of cold weather, being most active when putrefactive decomposition in sewers is presumably least so.

"10. Diphtheria is a contagious disease, transmissible from person to person and place to place, like small-pox and scarlet fever.

"11. The closing of schools and other places of public gathering checks an epidemic; and the isolation of the sick from the well, with the subsequent proper disinfection of the sick-room and its contents, extinguishes it.

"12. The data relied upon to prove a connection between sewerage and diphtheria either cover too short a period to be trustworthy, or are drawn from single cities having incomplete and defective sewerage.

"If these propositions be true, it follows as a necessary corollary that there is no direct relation between sewers and diphtheria."

These conclusions are based upon a study of the vital statistics of a large number of European and American cities and districts.

These are not at variance with any settled views as regards the origin of diphtheria. Many individuals have reported cases which seemed to originate from sewer-gas, but the most careful authorities have not been disposed to attribute to sewer-gas more than a predisposing influence.

A Better Fee than Billroth's.—Dr. C. Beard (retired), late of New Orleans, now of Boston, writes: "Referring to your mention, in your last number, under 'News of the Week,' of the fee, 25,000 francs, to be received by Professor Billroth, of Vienna, for an operation to be performed upon a wealthy banker of Alexandria, Egypt, in 1858 I was paid a somewhat larger sum—$5,000—for a cataract operation on Mr. Lastie Duprée, of Opelousas, La., and did not leave my home. Judging from the unction with which the announcement is made abroad, the foreign estimate of the value of distinguished services, at the present day, must be at least no higher than it was in this country before the war, and fees paid to distinguished men much lower than they were, according to my recollection, when I was in Europe in 1849–52."

There are Nine Physicians in the House of Representatives, according to the *Weekly Medical Review*, which journal at the same time hopes from them a benign influence on legislation.

News of the Week.

The Sultan of Turkey has decided to send a commission to M. Pasteur's laboratory to study his method of inoculation for hydrophobia. The members of the commission are Zocros Pasha and Hussein Bey, medical men, and Husni Pasha, veterinary surgeon. Zocros Pasha will present M. Pasteur with the Order of Medjidie and $2,000, a subscription from the Sultan for the Pasteur Institute.

Death of Dr. William L. Hardy.—The sudden and unexpected death of Dr. Hardy, of this city, has excited sorrow and regret among a very large circle. Dr. Hardy's name was a familiar one to the profession and public, and he had long been a faithful worker in the field of mental diseases. His death is believed to have been caused by the exposure and overwork incident to his duties as physician to the Tombs and city examiner of the insane. Dr. Hardy was born in this city on May 18, 1849, and was educated at the New York College. He studied medicine at the Bellevue Medical College, and at his graduation was appointed Inspector in the Health Department. He was afterward surgeon of the old Park Hospital, and of the city schoolship Mercury. In 1875 he was placed in charge of the Insane Asylum on Ward's Island, and he remained there five years. He was recently appointed by Mayor Grace one of the Board of Civil Service Examiners.

Clear Water in the Adirondacks.—Mr. Joseph T. Duryea, of Boston, writes: "I notice that a writer who reviews the book of Dr. Stickler on 'The Adirondacks as a Health Resort,' doubts the statement that in some regions the water is so pure that one might read a newspaper through seven or ten feet of it. Of course, if one could not read a newspaper seven or ten feet from the eye under any conditions, he could not read it through seven or ten feet of the purest water. Every person who has travelled much in the woods will remember springs in which he has seen labels lying on the bottom, fallen from bottles of claret hung by cords in the water to cool. There is such a spring near one of the Tupper lakes, and any number of them here and there can be seen. Let the writer visit Clear Pond, near Long Lake, or the chain of ponds on one of the routes between the Upper Saranac and St. Regis Lake. There is not a fisherman of any experience who has not seen the spots of a trout many a time through 'seven or ten feet of water,' in many a 'spring-hole.' The doubt is of small importance to me; but I would not like the expression of it by the reviewer to cause any doubt as to the accuracy of the contributors to a very useful book."

No Promises to Pay the Expenses of Foreign Delegates to the International Congress.—Dr. John S. Billings, of Washington, D. C., April 26, 1886, sends us the following explanatory note: "Before seeing your editorial of April 24th, my attention had been called to the statements of Dr. Petit. as to what he understood I had promised European physicians who might wish to attend the International Medical Congress in this country, and I had written to him to explain what I really did say. It now seems proper to send you the same information for publication, in order to do away with possible doubts and misapprehensions among physicians in this country. I did not make any promise, or express any belief, that the expenses of European physicians coming to the Congress would be paid by the United States, or by any other party than themselves. Even had I had such a belief, I should not have mentioned it as an argument to induce the Committee to select the United States as the place of meeting, for it would have seemed to me exceedingly bad taste to have done so. What I did say, in reply to the objection as to the expense of the journey, was, that I hoped and believed that arrangements could be made with some of the lines of transatlantic steamers by which the expense would be reduced. One of the English members of the Committee then spoke of the very liberal arrangements as to excursions, etc., which are made in this country in connection with scientific meetings, and asked me whether, at the meeting at Montreal of the British Association for the Advancement of Science, a free trip to Philadelphia and return was not given to the members, to which I replied that such was the case. I also said that while we should do our best to take proper care of our guests, it must be remembered that we should not be favored with government and municipal appropriations, as was the case at Copenhagen, but that the necessary funds must be raised by American physicians, and hence that we could not promise to rival the magnificent entertainments of the London and Copenhagen Congresses. I regret very much that my remarks should have been misunderstood by Dr Petit, who is, I feel sure, perfectly honest in his belief that his statements are correct. I can only account for the mistake by supposing that he is not as familiar with spoken English as he is with our literature. I had not seen his *feuilleton*, and have endeavored to correct the misunderstanding as soon as it was brought to my notice."

Forewarned, Forearmed.—"Good morning, children," said an Austin physician, as he met three or four little children on their way to school, "and how are you this morning?" "We darsn't tell you," replied the oldest of the crowd, a boy of eight. "Dare not tell me!" exclaimed the physician, "and why not?" "'Cause papa said that last year it cost him over fifty dollars to have you come in and ask us how we were."—*Texas Siftings*.

A New Dodge on Physicians.—A correspondent sends us the following: "Please call the attention of the profession to a little, black-haired crank, or blackguard, who makes appointments with physicians to meet Dr. Blank in consultation. The writer was by this token treated to an agreeable interview with two well-known physicians of our city, who had also received a visit and summons from the Gallic vagrant. I turn him over to your columns herewith."

Association of American Medical Editors.—The annual meeting of the Association of American Medical Editors will be held in St. Louis, May 3, 1886. The programme for the occasion has not yet been announced, but will embrace an address by the president, papers by well-known authors, and perhaps a banquet.

The Death of Dr. R. H. Benjaman, of Riverhead, L. I., is announced. He graduated in medicine at the Berkshire Medical College in 1842.

Dr. William H. Forbes has been elected Professor of Anatomy at Jefferson Medical College, Philadelphia, in place of Professor Pancoast, who recently retired.

The Corner-stone of the New Medical College Building.—As announced last week, the corner-stone of the new College building to be erected by the College of Physicians and Surgeons was laid last Saturday afternoon, with impressive and interesting ceremonies. The site of the building is at the corner of Fifty-ninth Street and Tenth Avenue. The exercises were opened with prayer by the College chaplain, Rev. S. H. Weston; Dr. John C. Dalton, President of the College, then lifted a metal box by a strap, gently deposited it in a square bed of fresh cement, and covered it with a marble slab. The box contained, so he told the people who watched him do it, several catalogues of the College, copies of the city newspapers and medical journals, the original letter of William H. Vanderbilt proffering the Trustees the gift of the new building, and the original resolutions of thanks in which the gift was accepted. Then Mr. George W. Vanderbilt, youngest son of William H. Vanderbilt, stepped forward and performed the ceremony of laying the corner-stone. An address by Chauncey M. Depew followed. After alluding to the enduring and wide-spread influence for good which results when wealthy men establish great charities, he said: "But how most wisely to invest the money which is to carry out a charitable purpose is not an easy problem. It is often partly wasted to gratify the vanity of the donor. Mr. Vanderbilt had become familiar by his own sufferings, so patiently endured that none but his intimate friends knew of them, with the beneficent effects of medical skill and the possibilities of its growth. With his strong common-sense he saw that here was practically an untried field, where the advancement of science might work out the most beneficent and benevolent ends. Libraries, hospitals, and art and literary institutions existed in numbers, each doing in its own way admirable work. While in the Old World governments fostered schools of medicine, here their only patrons were the profession, and there was not a single great endowment in the land. To build a college to be called by his name was a temptation, but in a city where so many excellent universities already existed he saw that the wiser use of his money was to develop and enlarge an old institution, whose age, traditions, and experience were of incalculable value, and constituted a permanent capital which wealth could not create. In selecting the College of Physicians and Surgeons he chose the oldest in years, and the equal in rank and equipment of the best." Mr. Depew then outlined the history of the College, its early struggles, and its influence on the progress of medicine in America for a century. Its founders established the first free dispensary New York ever had. Mr. Depew recited the incidents of the old struggle for supremacy with Columbia College, which became one of the political issues of the time, and ended in triumph for the Physicians and Surgeons. Then he said: "The College of Physicians and Surgeons becomes one of the strongest and best-appointed schools in the world through the medium of the splendid benefaction we this day commemorate. Upon these grounds, donated by William H. Vanderbilt, whose gift erects, furnishes, and endows a building equal to all the requirements of the present and the needs of the future, Mr. William D. Sloane builds the Maternity Hospital, and the generosity of his wife endows all the beds, making them free; while the four sons create the clinic, which will be a vast dispensary, giving without charge to the poor, for all time, medicines and the best professional attendance, as a memorial to their father—more grateful to him if living, and to his spirit now that he is dead, than stately shaft or gorgeous mausoleum. A private benefaction renders possible the construction and equipment of a medical college superior to any ever known in this country, and equal to the best in the world. With this endowment, and the impulse and inspiration which will follow it, New York will become the centre of medical learning, education, and acquirement for the American continent." Among the listeners were numerous students, the Faculty of the College, and many prominent physicians of the city. A delegation of Columbia College boys attended in a body, with blue and white ribbons streaming from their canes, and at the close of the ceremony they gave three rousing college cheers for the Vanderbilts collectively, Chauncey M. Depew, and Dr. McLane.

The Dose of Morphine in Infantile Convulsions.—Dr. C. S. Scofield writes: "I find by my notes, which were mislaid when I wrote the report of a case of infantile convulsions treated by injections of morph. sulph., that the amount used was $\frac{1}{12}$ gr., half of a $\frac{1}{6}$-gr. morphine tablet being used at each injection, instead of half of a $\frac{1}{4}$-gr. tablet. All the cases which I have seen reported were treated with a large single dose. I prefer small repeated doses as being safer."

Dr. B F. Harrison, of Wallingford, Conn., died on April 24th, in the seventy-fifth year of his age. He was a graduate of the Yale Medical School, and it is reported that part of his estate will go to that institution.

The Presentation of a Loving Cup to the College of Physicians of Philadelphia.—On Wednesday evening, April 14th, on the occasion of the ninety-ninth anniversary of the founding of the College, more than one hundred of the Fellows sat down together at dinner, Dr. S. Weir Mitchell, the president of the College, occupying the head of the table. After the cloth was removed, Mr. Horace Howard Furness, on behalf of two ladies, descendants of two of the founders of the College, presented to the College, in a happy speech, a massive silver loving cup.

Pasteur and His Patients.—M. Pasteur has been unfortunate in his treatment of the ten Russians bitten by a mad wolf, for three of them have already succumbed, but they were those who were the most severely wounded. Pasteur believes that the rabies of the wolf is more active than that of the dog, and that the period of incubation is shorter. He intends submitting the remainder of the Russians to a triple series of inoculation. Six persons from Finland have arrived at the Rue d'Ulm, and up to the present over seven hundred persons have been treated by him. The subscription in favor of the institute amounts to over $100,000.

Aural Hallucinations.—Alluding to Dr. Sexton's case, presented to the Practitioners' Society, and reported in The Record for April 3d, a correspondent writing from Millwood, Kan., states that he now finds this symptom in alcoholism so invariably as to regard it as pathognomonic. Dr. C., our correspondent, will note that Dr. Sexton's case had become one of cerebral disease, and that the hallucinations which occurred subsequently remained. We cannot agree with our correspondent that aural hallucinations depend on the impurity of the whiskey drunk in his neighborhood, since these symptoms are not unusual during the progress of delirium tremens.

Willard Asylum, which has upward of one thousand eight hundred insane chargeable to counties, has reduced its price per capita to $2.20 per week. At this rate the insane have the highest grade of care at a minimum cost to the counties. It is poor economy for any county to build and maintain an asylum when its insane can have better care at a much lower rate in a State asylum.

The School for Attendants, organized in the Buffalo Asylum for the Insane, is about to hold its first Commencement. Six attendants have completed the course of instruction, and have been found qualified to receive the diplomas of the school. The occasion will prove interesting as the first in the annals of the public care of the insane. The exercises will occur on Tuesday the 20th inst. The example of the Buffalo Asylum should be followed by other asylums of the State, and thus raise the grade of qualification of attendants in all our large asylums.

A New Sign in Auscultation.—Professor Pitres, of Bordeaux, indicates a new sign in auscultation. Dr. Davezac describes it as follows in the *Journal de Médecine de Bordeaux:* The patient is seated, and is auscultated in the dorsal region. An assistant places a sou on the thorax, in different parts, according to directions, and percusses. The ear of the auscultator listens at the opposed corresponding parts. The healthy side is first examined; then the side with pleurisy, where the note is much higher. A clear metallic sound indicates pleuritic effusion; when this sound is absent there is no effusion. —*British Medical Journal.*

Gambetta's brain was stated by Mr. A. Bloch, a few months ago, to be of unusually small size, weighing only 1,160 grammes, or 38.4 ounces. At the meeting of the Société d'Anthropologie of March 18th. Professor Duval added, further, some interesting details of its conformation and structure. In comparison with brains of subjects who were known to have been of deficient mental powers, such as possess only a feeble development of the third frontal convolution, Gambetta's brain was found to have an extreme development of this convolution, and the fissures very numerous and very complicated. This development furnishes confirmatory evidence of Broca's discovery of the localization of speech in this convolution. In addition to other peculiarities, the right quadrilateral lobe was found to be very complicated, with numerous fissures in its lower part; and the occipital lobe was extremely reduced, especially on the right side. —*Science.*

Reports of Societies.

MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND.

Eighty-eighth Annual Convention, held at Baltimore, Md., April 27, 28, and 29, 1886.

Tuesday, April 27th—First Day.

The Eighty-eighth Annual Convention of this body was convened in the medical library, Athenæum Building, corner St. Paul and Saratoga Streets, Baltimore, Md., Tuesday, April 27th, at 12 M., Dr. John. R. Quinan, President, in the chair, and Drs. G. Lane Taneyhill and Robert T. Wilson, Secretaries.

THE PRESIDENT'S ADDRESS

was the first order of business after organization. It was

ON THE CHARTERED RIGHT OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND TO ISSUE LICENSES TO PRACTISE IN THE STATE.

After a few preliminary remarks, the speaker proceeded to lay before his hearers the results of his examination of the legal records of the State bearing upon the above subject. As early as 1795 the physicians of Maryland saw the need of protection against quackery. As the result of meetings summoned through the press, the Medical and Chirurgical Faculty was finally incorporated under its present charter in 1798. Power is granted to the Faculty through its Medical Board of Examiners "to grant licenses to such medical and chirurgical gentlemen as they, either upon a full examination, or upon the production of diplomas from some respectable college, may judge adequate to commence the practice of the medical and chirurgical arts; each person so obtaining a certificate to pay a sum not exceeding ten dollars." No one practising was allowed to receive payment for his services without having obtained such certificate, under a penalty of fifty dollars for each offence, to be recovered in the county court where he may reside by bill or presentment and indictment, one-half for the use of the Faculty, and the other for that of the informer.

In 1801 they secured a supplementary act to enforce under penalties the same power. In 1816 and 1818 further slight amendments were made. In 1821 persons not licensed were disabled from suing or receiving compensation for professional services. In 1838 an act was passed by the Legislature, entitled "An Act to authorize Thompsonians or Botanic physicians to charge and receive compensation for their services and medicines," which made it lawful for each and every person being a citizen of the State to charge and receive compensation for their services and medicine in the same manner as physicians are now permitted to do. He cited the whole of this absurd act to show the inconsistency between the title and body of it—one for the benefit of a certain class of quacks, styling themselves Thompsonians, the other for the benefit of every white citizen of Maryland who chose to assume the rôle of doctor. The inside history of this legislative monstrosity was, he had been told, "that a bill of this kind for the benefit of these charlatans was gravely offered by some Solomon, and its absurdity was so transparent that some waggish member tacked on its present body to the original title, and made a hybrid equal to Barnum's mermaid, thinking thus to kill off its supporters."

This, however, with the early death of Thompsonianism, soon became inoperative and void, and is now only remembered as a grim legislative joke. These are the only statutes on record, except unimportant ones of 1861 and 1862. It is thus evident that since 1798 there has been no legislative act offered or passed to infringe upon or impair the power of this Faculty to require licenses throughout the State (except the absurdity of 1838, now inoperative); but, on the contrary, many acts secured by

the efforts of this Faculty to confirm, enlarge, and enforce this power, and he confessed that, as he had been led to infer from the opinions of others that our statute-books bristled with hostile legislation, he was the more agreeably surprised at the result of his examination. Nor did the privilege granted to the College of Medicine of Maryland—later the University of Maryland—to grant diplomas render the licensing power of the Faculty nugatory, this charter being subsequent to ours, and, of course, not impairing a prior contract. Such a thing would violate the Constitution of the United States and Bill of Rights of the State. The above institutions sprang from this Faculty, and always showed warm attachment to it. The governing power of the College of Medicine consisted in greater part of the Board of Examiners of this Faculty. The Medical and Chirurgical Faculty constituted its patrons and visitors, and the President of the Faculty its chancellor. The Faculty of the College was required to report biennially the progress of the College to this body. All this shows that no interference with the licensing power of the Faculty was intended, and *that act of* 1798 is to-day the law of the *State, and can be enforced as such.*

The President's address was listened to with rapt attention and frequently applauded. It was a genuine surprise to everyone present, as it is a prevalent impression among the Maryland physicians that the right to regulate the practice in the State, and to issue licenses therefor, has long since passed out of the hands of the Faculty. The subject of a medical law in the State is one which has lately been much in the minds of the physicians here, and the difficulties of securing acceptable legislation are generally appreciated. If, therefore, a forgotten law can be revived, in which we get rid of the bugbear of irregular practitioners and their recognition, it will prove to us a great boom. The conclusions of the President were therefore received with great applause.

After adopting a vote of thanks for the address, Dr. Waters moved the appointment of a committee, consisting of the President and two others, to investigate the matter still further and report.

Dr. P. C. Williams inquired as to the expense connected with such an investigation and the employment of legal advice.

Dr. Gundry thought the law had lapsed by neglect to enforce it, and that moral sentiment would be an insuperable obstacle to its enforcement.

Others spoke in favor of the motion, which was adopted. Drs. Waters and B. B. Browne were appointed to act with the President on the committee.

THE TREASURER'S REPORT

showed the assets of the Faculty to amount to $9,549.40. This includes value of library, estimated at $9,000. The total receipts for the year were $1,628.29 ; disbursements, $1,769.79, leaving a deficit of $141.50. The building fund of $500 had been reduced, by the expenses of moving last October to our present quarters, to $192.70. The Library Committee had received $539.81 for the maintenance of the library. Nine members had been added, 2 resigned, 4 dropped for non-payment of dues, 5 died.

The Board of Examiners presented the names of seven persons—one a lady, the first who has applied—who are candidates for membership.

The Library Committee presented an interesting report, showing a very prosperous condition of the library and very satisfactory growth during the year. Considering the very insignificant resources at command, the development of the library may be considered very remarkable. The number of bound volumes now amount to 5,000, 830 having been added during the year, chiefly through the generosity of individual donors. Sixty-six journals are now regularly received, besides a large number of foreign and domestic society transactions. The donation of several portraits, old diplomas, and other interesting relics was also acknowledged.

WEDNESDAY, APRIL 28TH—SECOND DAY.

After the reading of the minutes, Col. George E. Waring, of Newport, R. I., proceeded to deliver

THE ANNUAL ORATION,

the title of which was

THE REMOVAL AND DESTRUCTION OF ORGANIC WASTES.

The speaker began by stating his embarrassment in finding a suitable subject for a medical audience, as he was absolutely ignorant of nearly every detail of the science and practice of the art. He could hardly claim even a subjective knowledge of the latter, as among the good things which had befallen him had never been the training of a good patient. He belonged to a profession that was called on to do some of the rough mechanical work on which the improvement of certain conditions of living depended.

In discussing his subject he very properly referred to the influences of organic waste on the health of communities, and of their association with the advances of civilization. The diseases of civilization were those of bad sewerage. Their prevention was the removal of the cause. The cardinal rule should be that every organic substance, of whatsoever sort, when its usefulness has passed, and its stability is threatened, should be immediately and completely removed to a distance. Being so removed the safety of the household or community by which it was produced is essentially assured. Its subsequent history is interesting chiefly with reference to those into whose presence we may have sent it. Their safety is to be secured by insuring its destruction under conditions which will not favor the pernicious results attendant on restricted and aborted decomposition. It seemed prudent to predict that the world will before long accept what now seems to be the demonstrated proposition that all that we need consider with regard to municipal organic wastes, to prevent their interference with health and life, is to get them out of our neighborhood while still in their fresh condition, and then to secure their rapid resolution into their inorganic elements. Briefly, speedy and complete removal with speedy and complete decomposition. It was not simple nor easy to apply such a formula in its entirety, owing to prejudices and preconceived ideas.

He then concluded by sketching a detailed plan for the more effective sewerage of Baltimore.

Dr. Randolph Winslow, in the Surgical Section, discussed the following subjects :

TREATMENT OF PENETRATING WOUNDS OF THE ABDOMEN AND OF INTESTINAL OBSTRUCTIONS, OPERATIONS FOR PYLORIC STENOSIS, AND RESECTION OF THE LARGE INTESTINES FOR CARCINOMA.

Under the first head was mentioned Dr. John B. Hamilton's remarkable and successful case of laparotomy for pistol-wound of the abdomen. He operated three hours after the injury, suturing eleven wounds in the small intestine, two in the ascending colon, and ligating a bleeding artery in the mesentery. On the seventh day fæces passed per anum. On the twelfth the ball was evacuated, and a good recovery ensued. Allusion was also made to the case of Dr. A. V. Park, of Chicago, who performed laparotomy unsuccessfully for penetrating gunshot wound of the abdomen in a boy, aged sixteen, entering the small intestine in two places and tying a small mesenteric artery. Death ensued sixteen hours later from peritonitis, and the autopsy revealed an undiscovered contusion of the rectum. The chances for success in this case were much diminished by the length of time between the injury and the operation, and the moving of the patient twice, which necessitated his travelling a number of miles.

The remarkable experience of Dr. Edmund Andrews, also of Chicago, was commented on. We have here four cases of penetrating wounds of the abdomen, occurring

in Chicago. Two recovered promptly without any operation, one recovered in spite of laparotomy, and one died notwithstanding it. Truly an interesting commentary. By far the most interesting contribution to the elucidation of the subject is Dr. Dennis' elaborate article; but the speaker took issue with him when he says, "all these patients are necessarily mortally wounded, if penetration and perforation have taken place," numerous cases having recovered after intestinal as well as stomachal perforation. Quoting Otis' statement that there was no incontestable instance of recovery in penetrating gunshot wounds, Dr. Winslow thought this might apply in military, but it did not in civil practice, probably because the pistol figures much more largely in the latter. Dr. Winslow criticised quite severely Dr. Dennis' method of dealing with a stab-wound of the abdomen, and thought it was carrying the principle of ocular inspection a little too far. It is just such a procedure which is likely to bring discredit upon the operation of laparotomy in these cases of abdominal injury.

The discussion upon this subject at the New York Academy of Medicine, last December, was commented on. In summarizing the prevailing professional opinion in regard to the treatment of penetrating abdominal wounds, it appears that there is an almost unanimous consent to the propriety of performing laparotomy when there is reason to believe that serious injury of any of the hollow viscera has occurred, or that hemorrhage is taking place; but there are certain cases in which the nature of the lesions is doubtful, and it is in such cases that diversity of opinion exists. For my part, I am more firmly convinced than ever that where there is a strong probability that serious intestinal injuries have been received, a laparotomy ought to be performed; but I think a certain amount of conservatism ought to be indulged in, especially in regard to wounds from bullets of small size or from stab-wounds, many of which either do not penetrate the viscera or produce such small holes as to do no material harm. He took this opportunity to mention one fact in regard to the suturing of intestinal wounds, and that was, never to bring the cut surfaces together edge to edge, but by means of the Lembert suture invest the peritoneal borders so that narrow bonds of peritoneum are approximated. When this was done union was effected easily and effectually.

Under the second head Dr. Winslow said the confusion in regard to treatment arose from inability in a large majority of cases to make an accurate diagnosis. He characterized Jonathan Hutchinson's abdominal taxis under anæsthesia as a rather rude and unsurgical method. In Dr. Winslow's opinion a case of intestinal obstruction should first have the benefit of rational medical treatment, first by laxatives, to overcome a possibly obstinate constipation; then by copious enemata, with the patient in the genupectoral or completely inverted position. If the symptoms are not severe, belladonna or opium may be administered in large doses; but if the patient present urgent symptoms—severe pain, obstipation, constant vomiting—especially if the character of the latter become feculent, no time is to be lost. The abdomen should be opened in the linea alba, below the umbilicus, the cause of the arrest ascertained, and the constriction released. He thinks a strangulated bowel within the abdominal cavity should be treated pretty much as a strangulated bowel outside of it.

If a patient with hernia present symptoms of strangulation, an anæsthetic is administered and gentle taxis employed. If this fail, most surgeons proceed at once to kelotomy, as in internal hernia and other obstructions. It is not often possible to locate either the nature or the seat of the lesion: he does not think much manipulation of the abdomen should be allowed, lest harm, and not good, result; but after the failure of enemata and laxatives, laparotomy should be performed, and the incarcerated bowel released. He regards enemata under heavy pressure, as advised by Illoway, of Cincinnati, as fraught with great danger. The bowel may rupture, or a gangrenous intussusception may be thrust backward into the peritoneal cavity. Dr. Winslow then alluded to the case already reported by him in the *American Journal of the Medical Sciences*, in which he had opened the abdomen of a young woman suffering for seven days with obstruction, stercoraceous vomiting, etc., and released a constriction of the ilium, with complete and speedy recovery; also the case of Dr. Frank West, of Baltimore, who had operated on account of the adhesion of a knuckle of intestine in the femoral ring, without producing symptoms which could be recognized from the outside. A good recovery ensued here also. A third case of laparotomy had recently been done in this city, but was unsuccessful.

Four operations of pylorectomy have now been done in this country, two being in this State, but all proved fatal. Two cases of digital divulsion of the pylorus have been done in New York, both dying.

Weir, of New York, had successfully resected five and a half inches of the sigmoid flexure for carcinoma. Lange, of New York, had twice done it previously without success. In Europe it had been done thirty-two times with sixteen recoveries. According to Weir, Kocher, of Bern, removed five feet of gangrenous intestine from a patient, who was discharged well in eighteen days.

Dr. J. W. Chambers presented the second paper, on

REMOVAL OF INFLAMMATORY AND SUPPURATING GLANDS OF THE NECK,

illustrating it by several cases treated at Bay View Hospital. The surgical fear of deep-seated cellulitis of the neck, he said, has lost its terrors under the influence of antiseptic surgery; and with anæsthetics and deliberate dissection with the handle of the knife and the fingers, bleeding and shock were not now prominent dangers. We were only limited in the extent to which we should attempt the removal of these glands by anatomical considerations. Even the latter were shown, by some of the cases reported, to be more elastic than many were willing to believe. In each case there was a transient rise of temperature within the first twenty-four hours, but no signs of septic absorption.

Dr. Branham presented the third paper from the Section, entitled

CLINICAL NOTES ON GENITO-URINARY SURGERY, FROM BAY VIEW HOSPITAL.

Among the conclusions set forth was this:

THE UNCERTAINTY IN THE DIFFERENTIAL DIAGNOSIS BETWEEN SOFT AND HARD CHANCRE

is so great in hospital patients, where the history is of little value, and where the sores have usually been irritated by caustic, filth, and continued exercise, that we should always wait for secondary symptoms. If internal medication be begun before the latter manifest themselves, it will be imperfectly carried out, because patient and physician are both in doubt as to the nature of the malady.

Among those elected to membership to-day was Dr. Amanda Taylor Norris, a graduate of the Woman's Medical College of Philadelphia, a native of Maryland and Professor of Materia Medica, Therapeutics, and Chemical Medicine in the Woman's Medical College of Baltimore. But one ballot was cast against her, which was rather remarkable for so conservative a place as Maryland, she being THE FIRST WOMAN WHO HAS APPLIED FOR MEMBERSHIP IN THE SOCIETY. It will be recalled that two colored physicians were admitted two years ago without opposition.

(To be continued.)

Dr. Saundby says that the styptic taste of tincture of perchloride of iron may be disguised by administering it in sweetened milk. This mixture has the further advantage of not affecting the teeth.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 26, 1886.

LAURENCE JOHNSON, M.D., VICE-PRESIDENT, IN THE CHAIR.

DR. A. B. JUDSON read a paper on

WHITE SWELLING OF THE KNEE.

in which he advocated the doctrine that it was essentially an inflammatory affection, and that an inflamed organ or tissue demanded arrest of function in the treatment, if the best results were to be obtained; that inflammatory conditions were relieved or removed by arrest of function wherever it could be secured.

The essential feature of the treatment for diseases of joints should, therefore, be fixation, and to obtain this in the cases of white swelling of the knee he had devised a very simple, inexpensive, readily adjusted, and in his hands efficient splint. This was a simple steel retentive splint, consisting of a posterior upright, occupying the greater part of the length of the thigh and leg, and four arched cross pieces, making pressure at the upper and lower part of the entire limb behind and pressure in front above and below the knee. He did not use plaster-of-Paris, and believed that better results could be obtained by simpler means.

Prolonged fixation with disuse of a joint would not produce anchylosis, provided the joint itself was free from disease. Of course, it would be followed by stiffness, but that would yield by persistent passive movements, and was entirely different from anchylosis. The anchylosis which followed joint diseases and was caused by the final products of inflammation was best prevented by reducing or removing the inflammation, and to do this most effectually arrest of function was essential.

Fixation applied to a joint would, so far as the joint was free from disease, be powerless to add to the ultimate degree of anchylosis, and, so far as the joint was diseased, it would diminish the ultimate anchylosis by arresting inflammation and preventing an excess of its products.

On these premises thorough fixation was required in the treatment of articular ostitis. Dr. Judson thought it was impossible to establish the statement that motion was required to prevent inflammation.

In the treatment of joint disease, in the lower extremities particularly, another important function must be considered, namely, that of supporting weight and concussion. Protection of the articular surfaces from pressure and concussion was very important, and to accomplish this most certainly the best method was to convert the affected limb into a pendant member, putting it into very much the same condition, in this respect, as were the upper extremities. To bring this about, the apparatus which had served him the best was Thomas' splint, which was really an ischiatic crutch, and a high sole upon the shoe worn on the foot of the healthy limb. The crutch was to be worn only when the patient was up.

When these indications had been thoroughly met, Dr. Judson believed that the patient had received the highest degree of assistance which surgery could afford, and the conclusions reached by the author of the paper were such as naturally follow from the premises and the outline of the argument given.

DR. J. F. RIDLON complimented the author of the paper because it had seemed to him that orthopædists in general had endeavored to devise apparatus which was so complicated and expensive that no one except themselves could manage it. The splint exhibited was so simple that any parent could manage the treatment effectually between the visits of the surgeon. It also was inexpensive, which was a very important item, and it could be used with some form of apparatus that acted as a crutch.

All that was required, in most cases, was fixation; only a very few cases required traction. When these patients were out of bed some form of apparatus was required to prevent motion during locomotion. Dr. Ridlon had been unable to secure fixation by means of Thomas' splint without the aid of some other apparatus.

The chief, if not the only criticism he would offer on the paper, was with reference to Dr. Judson's condemnation of plaster-of-Paris. In his hands a certain number of cases, probably of syphilitic origin, had done better in plaster-of-Paris dressings than with any form of apparatus which he had used. There was one idea, however, which should be eradicated, and that was with reference to expense; the plaster-of-Paris was an *expensive* method, for the reason that to be effectual it must be changed every two or three weeks, whereas a steel brace would last throughout the course of the disease.

With regard to elastic traction Dr. Ridlon thought more had been claimed for it than it was justly entitled to.

In gouty joints motion was desirable, and the articulations were benefited by as much exercise as they could get; but in pure chronic joint disease, where there was fungoid degeneration, motion with elastic traction did harm. Although the simple splint exhibited did not protect the joint during locomotion in all cases, he was sure that in the vast majority, if put on carefully, and the patients were treated to a little extra confinement to the bed, and, when up, wore a high shoe upon the well foot, etc., good results could be obtained and the patients would be cured. The danger of anchylosis he regarded as nothing at all; he had never known of a case of anchylosis occurring as a result of fixation. If, however, anchylosis must occur, it was a mistaken idea that it should be allowed to occur with the joint at a slight angle; the limb should be straight. He had never met with a case in which there was lengthening of the limb.

DR. JUDSON said, with regard to lengthening of the limb, that although not personally familiar with many cases, he was not surprised to find it in the case reported, because it had been observed by Howard March, who, in 1877, directed attention to its occurrence, and by Berry, who had published a series of hospital cases in which it was found that in over one-half there was more than one-half an inch of lengthening.

He did not wish to condemn plaster-of-Paris severely, as he regarded it, through the labors of Dr. Sayre, as one of the greatest boons in surgery, and he was not surprised at Dr. Ridlon's success in the use of plaster-of-Paris. His only reason for preferring a steel apparatus was that when watchfully applied the bone could be more closely approximated, and a closer grip obtained, which would give a firmer fixation than could be expected from the plaster dressing. After all, the fact remained that the skilful surgeon, understanding the principles on which treatment should be conducted, would get good results with almost any kind of mechanical apparatus.

UNFINISHED BUSINESS.

Under this head the *Comitia Minora* reported and recommended that the Society approve of a bill, pending in the Legislature, entitled "An Act to Regulate the Licensing and Registration of Physicians and Surgeons, and to Codify the Medical Laws of the State of New York." The design of the act was to remove obstacles which, from time to time, had been encountered in attempting to execute the medical laws now upon the statute-books. The recommendation was adopted.

THE VICE-PRESIDENT announced the death of

WILLIAM HARDY, M.D.,

in a few appropriate remarks.

The Chair also appointed Joseph D. Bryant, M.D., to read a memoir of Gaspar Griswold, M.D., M.R.C.S.

The Society *disapproved*, by a vote on the question, of the reading of any communication before it

ON ANY MEDICINAL PREPARATION OR ARTICLE THAT HAD BEEN PATENTED.

Remarks were made by several members, after which the Society adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, April 22, 1886.

ALEX. S. HUNTER, M.D., CHAIRMAN.

DR. H. J. BOLDT read a paper on

CARDIAC NEUROSES WITH OVARIAN AND UTERINE DISEASE,

in which he referred to functional disturbances of the heart unaccompanied by organic changes. These might arise from disorders of the cardiac ganglia, or might be of reflex origin, and to the latter class of cases attention was directed. According to Dr. Boldt's observations, cardiac neuroses were present to a greater or less degree in about eight per cent. of the cases of uterine and ovarian disease, and occasionally cases were met with which presented symptoms that were referred to the heart alone; but disturbances of the uterus or its adnexa were associated, and the symptoms were removed by treatment of the pelvic organs.

The most frequent neuroses were palpitation, disturbance of rhythm or irregularity, intermittency or distinct loss of a beat, and angina pectoris.

The first was by far the most common, and might be more or less constant, or occur in paroxysms. Well-marked intermittency was very likely to be accompanied by palpitation, and if permanent, was probably indicative of organic cardiac disease; yet such cases occurred in which organic disease of the heart was absent.

With regard to angina pectoris, there existed a difference of opinion as to whether or not it could occur independently of organic disease of the heart.

Dr. Boldt then reported briefly several cases which he regarded as illustrations of cardiac neuroses associated with uterine and ovarian disease, and in which symptoms referable to the heart were relieved by treatment of the pelvic disorders. So far as the cardiac symptoms were concerned, the cases did not differ from those of like character depending on other causes.

DR. E. H. GRANDIN said that there seemed to be, at first sight, a clear connection, in Dr. Boldt's cases, between the cardiac symptoms and the disorders of the pelvic organs. He had frequently met with cases in which cardiac palpitation, intermittent pulse, etc., had been associated with uterine and ovarian disease; but he had not felt quite certain that they bore the relation to each other of effect and cause, for the reason that he had encountered the same symptoms in cases where the uterus and ovaries were healthy. Ordinarily he had found that these cardiac disturbances were associated with gastro-intestinal derangements. There were cases, however, in which cardiac symptoms, such as had been mentioned by Dr. Boldt, existed, and doubtless were due to the fact that the patients were suffering from uterine and ovarian disease. But he did not think that one was justified in making an examination of the reproductive organs, if no other evidence of disease of these organs could be obtained than that referable to the cardiac disorders. The particular point which he wished to make was that the stomach and intestines were more frequently at fault in this class of cases than either the uterus or the ovaries.

DR. BURRALL referred to a case which illustrated, in a remarkable way, reflex disturbances which were entirely relieved by free menstruation.

DR. H. C. COE said that it must be extremely difficult to distinguish between obscure cases of hysteria and cases of severe cardiac disturbance. The symptoms, palpitation, and pain referred to the cardiac region, were quite common in all disorders of the pelvic organs. He had not been very much in favor of the doctrine of reflex uterine neuroses, having never seen more than five or six cases in which cardiac disorders were associated with laceration of the cervix, etc. During a single year, at the Woman's Hospital, he met with three cases of sudden death after minor operations on the pelvic organs. In one case the diagnosis of fatty heart was made; but in another nothing could be found to account for the death. Whether or not there was any special connection between the disease of the pelvic organs, the heart, and the sudden death, he was not prepared to say.

DR. GOELET had frequently had patients object to taking ether for such operations as dilatation of the cervix, saying that they had been told that they had heart disease, and that they had been troubled very much with palpitation, pain, etc. Although these patients had suffered from cardiac disturbances, he had found that, in most of them, there was no evidence of organic disease of the heart.

DR. H. GRISWOLD referred to a case in which there were well-marked anginal symptoms associated with uterine disorder. The patient had been operated on, rather unsuccessfully, for laceration of the cervix, and subsequently suffered from repeated attacks of endometritis with distressing cardiac symptoms, which promptly disappeared on treatment of the uterine disease.

DR. BOLDT remarked, with regard to Dr. Grandin's statement, that he said an examination should be made only when no other cause for the neurosis could be found. With reference to Dr. Coe's remarks, he did not wish to convey the impression that laceration of the cervix was the cause of cardiac neuroses; that is, he did not believe that cardiac neuroses occurred with laceration of the cervix so frequently as had been indicated by some writers.

DR. F. A. BURRALL then read a paper on

ARTIFICIAL SUBSTITUTES FOR WET-NURSING IN PRIVATE PRACTICE,

in which he first referred to the best method of feeding infants, namely, nursing by the mother. The next test, according to most writers, was wet-nursing, although strong objections had been made to rearing infants by the aid of a wet-nurse; and they were such as to make him believe that this plan did *not always* stand second best to nursing by the mother. Dr. Burrall also discussed the question of the propriety of allowing an infant to be nursed by a syphilitic woman. Although it was doubtless true that wet-nursing was to be preferred to artificial food, yet extreme care must be exercised with regard to the choice of a nurse. The moral objections to wet-nursing were usually overlooked, but Dr. Burrall regarded them as very important. By many it was believed that the moral and intellectual qualities of the nurse were transmitted to the infant. Again, the moral effect upon the mother produced by nursing her own child ought not to be disregarded.

With regard to artificial food, Dr. Burrall believed that the results obtained by its use were very much influenced by the surroundings and the hygienic care of the children; that is, better results would be secured in well-regulated and well-to-do families, than among families which did not offer to their children the advantages attending such care.

Dr. Burrall then referred briefly to several of the artificial foods in common use, and also to several formulæ that had been given for preparing cow's milk to make it best adapted to feeding infants.

He regarded it as important to indulge in as little night-feeding as possible, and believed that night-feeding should be discontinued as soon as it could be.

In general, the practice was to feed infants too frequently and too much, rather than at too long intervals and too little.

No formula could be used exclusively for the preparation of food best adapted to each child. But, with our

present knowledge, wet-nursing could usually be safely avoided.

Dr. Dawbarn gave something of the comparative analyses of cow's and human milk. He thought that if starchy material was to be added to cow's milk probably Dr. Jacobi's formula for the preparation of barley-water was the best, but he did not use any starchy substance in the management of young infants.

He spoke of the artificial foods, and also of the faults belonging to condensed milk diluted, such as excess of sugar, etc. He would do away with the nursing-bottle altogether, and feed with the spoon. He favored the free use of cool, not cold, water in the intervals between feeding, in cases of summer diarrhœa.

Dr. Dessau was opposed to all foods as substitutes for wet-nursing. He approved of the use of condensed milk, such as is served at private residences in this city (not that put up in tin cans), instead of cow's milk, because in the process of its dilution it could be always made of a uniform strength, which could be changed as the age of the infant advanced. His usual mode of preparing it for food was to add a tablespoonful to a nursing-bottleful of tepid water, with a pinch of salt. It was less likely to undergo chemical changes in warm weather than cow's milk, and did not require boiling nor the addition of an alkali. To a certain extent the disturbing influence of casein was avoided by using condensed milk, because in the process of its preparation the casein was acted upon in such a manner as to prevent coagulation thereafter by the action of the fluids of the stomach. It had served him better than any food he had used, and was the only preparation which he would recommend as a substitute for wet-nursing. He had used it largely at the New York Foundling Asylum, and with satisfactory results.

Dr. H. D. Chapin agreed with what had been said concerning artificial foods. They could be easily imitated. Casein, the most disturbing substance, could be attenuated by boiling, or digested by peptonizing the milk with the addition of an alkali; but it was not yet decided whether or not this method was a good one, because of the large quantity of alkali required. Kumyss had, by some, been added, for the purpose of disposing of the casein.

Dr. Winters said, with regard to wet-nursing, that anything should be welcomed which would obviate the necessity of the child having a foster-mother. He had not, for a number of years, found it necessary to employ wet-nurses. One reason why artificial feeding was so unpopular was because an attempt was made to substitute something unnatural for mother's milk, namely, artificial foods. There was no artificial food which was natural to the child, all contained more or less of starch; and if that was certainly transformed so that it could be digested, the nutritive power of the food was destroyed by the process, and the consequence was the production of an inferior article. No artificial food would sufficiently nourish a child without the addition of cow's milk.

Why was not cow's milk used more, and, when used, why did it fail so frequently? In the first place, sufficient care was not exercised in getting the milk. Secondly, nearly all bottle-fed children were over-fed; excessive feeding, therefore, was a cause of failure. Third, too rapid feeding was accountable for failure in many cases. The child should be fed with the same care and time when the bottle was used as when it was nursed by its mother.

Dr. George B. Fowler advocated the use of mother's milk first, cow's milk second, and then spoke of the different methods that had been resorted to for making it as near like mother's milk as possible. He thought it quite possible that many times too much alkali was added in the method by pancreatizing and the use of an alkali, as only a distinct alkaline reaction was required. He had found that the addition of a small quantity of pepsin to cow's milk, and then heating it, gave a clot which could be easily broken up, and when crushed it did not reclot in the stomach, and therefore had answered an excellent purpose. He believed that the milk obtained now in this city, thanks to the vigilance of the Board of Health, was equal to that which could be obtained in the country.

Dr. B. F. Dawson said that it was absolutely easy to bring a child up without the aid of mother's milk and without wet-nursing. The frequency, the quantity, and the rapidity with which children were fed were of as much importance as the quality of the food. He believed that the entire evil in feeding children consisted in feeding them too much at a time, too often, and too rapidly.

Cow's milk was all that was necessary, with something added to prevent the coagulation of the casein; if anything more was to be added it should not be water, but fat—for example, a piece of pure fresh butter as large as a hazel-nut at each meal. He said that if an infant was only looked upon as an animal that could take care of itself if let alone, all those who had to do with the rearing of children would get along much better than they did. He regarded it as important that the child should have plenty of water between meals.

A child should not be fed in the night, if possible to avoid it. The child should not be allowed to sleep at the breast. Make the interval between meals as long as possible both day and night—three, four, six, or even twelve hours. Never give an infant food until certain that it is hungry. His rule was to have the child fed at seven in the evening, once during the night—at two o'clock—and the next time in the morning, at six o'clock or thereabouts.

Dr. Winters said that the healthiest infants he had ever seen had not been fed during the night. In early infancy children occasionally might be fed at night, but in the majority of cases when the child awakens, and it is supposed that it is hungry, the application of a dry napkin or giving it a little water would be sufficient. After the first two months, as a rule, children did not require to be fed between ten o'clock in the evening and six or seven in the morning.

As to day-feeding, he should be governed by the instinct of the child, taking care that crying was not mistaken for hunger. He directed that the child should never be awakened for feeding, let the time be four, six, or more hours. Usually children were fed every two or three hours, and feeding every two hours was very likely to bring on indigestion. *On an average*, once in three hours during the day, and during the night at as long intervals as possible, and indigestion will rarely occur. A child should never be allowed to sleep while being nursed by its mother.

Dr. Burrall, in closing the discussion, said it was doubtless true that barley-water was constipating to some children and laxative to others.

The Section then adjourned, to meet on the fourth Thursday in October.

SECTION IN SURGERY.

Stated Meeting, April 12, 1886.

Stephen Smith, M.D., Chairman.

The Chairman reported, for discussion, a method of treatment of

FISTULA IN ANO,

in which he gave the details of an operation as performed successfully in several cases. He regarded the operation as applicable to all varieties of fistula in ano, and the average time of cure had, in his cases, been ten days, by a single operation, which consisted in laying the fistula open completely in all directions, completely excising the lining membrane, and then bringing the surfaces into thorough coaptation. He prepared his patients by

giving an ounce of castor-oil for two successive days before the operation, omitting it on the last day, on which an opiate was given at bedtime. The diet consisted of milk. The operation was performed with technical antiseptic details.

Shave the anal region and irrigate it, and also all the folds of the rectum, with the bichloride solution. Put a clean sponge, having a string attached to it, into the rectum. Place the patient upon the side corresponding to the external opening of the fistula. Incise the fistula in the usual manner, dissect away the pyogenic membrane throughout the tract, and from whatever pockets may have formed. Cut away the ragged margins and leave a clean, healthy surface for approximation and union. Control the hemorrhage completely before closing the wound. Secure perfect apposition of the margins of the wound and the deeper surfaces, with superficial and deep sutures. Introduce a drainage-tube, which is usually removed on the day following the operation. Use an opium suppository. Confine the patient upon the back, with the limbs straight. Keep the bowels quiet for five or six days. Restrict the diet to milk.

Dr. A. Jacobi asked, What does the most modern surgery think of the contra-indication to operating for fistula in ano in cases of advanced or incipient phthisis? The old view was that the existence of phthisis was a contra-indication to operating upon fistula in ano; or, in other words, that to operate upon fistula in ano in phthisical patients was not justifiable. He regarded it as an important question, and would be pleased to hear of it in the light of modern surgery.

The Chairman said, that if it were left to him to answer, he would say in reply to Dr. Jacobi's question, that surgeons in our times were inclining very much to operate in tuberculous cases. Wherever they could remove tuberculous conditions, as, for instance, in a joint, by excision and amputation, they did not hesitate to resort to operative procedure. So far as his observations went he did not believe that these fistulæ were, as they were at one time regarded, drains through which the system obtained relief by the exit of deleterious material; and he believed that they were drains only in the sense of affording an escape to discharge which weakens the patient. He had never seen any bad results follow surgical operations under these circumstances, but he had seen immediate good results follow the operation.

He referred to one case in which the patient had had repeated hemorrhages, and it was said by competent physicians that there were large cavities in the lungs. This patient had caries of the wrist-joint, which was the chief source of complaint. Amputation of the wrist was performed, and the patient recovered very promptly, and had since remained in an apparently healthy condition.

Dr. Jacobi then asked if he was to understand that surgical opinion had changed somewhat with regard to the operation for fistula in ano in cases of consumption?

The Chairman said that, so far as his knowledge of the opinion of surgeons went, it was one of the operations which surgeons would regard as justifiable in cases of phthisis.

Dr. Jacobi said he could see that there was a difference between the relation of fistula in ano to pulmonary consumption, and the relation of tuberculous bone to pulmonary consumption. Tuberculous bone might be not only a constant cause of new infection, but also be the original seat of the disease, which, if removed, would facilitate recovery. It was probably not so with regard to fistula in ano. He referred to the subject especially for the reason that it had been taught, and we had been led to believe, that fistula in ano occurring in phthisical subjects was not to be interfered with surgically. It appeared, however, from what the Chairman had said, that he did not hesitate to operate in such cases.

Dr. J. C. Peters remarked that it was worthy of note that in the older operations it was customary simply to lay the fistula open, whereas the operation described by Dr. Smith contemplated removing the lining membrane of the sac, in the expectation of saving the patient from the dangers which attended the old method of procedure.

The Chairman said that unless it could be proved that fistula in ano was a necessary drain, and that its closure would precipitate a tuberculous condition of the lungs, certainly modern surgical methods rendered it wise to rid the patient of such a source of exhaustion.

Dr. Robert T. Morris then reported a case of

AMPUTATION OF THE LEG OF A MAN AGED OVER EIGHTY-THREE YEARS.

He regarded it as one of the test-cases in antiseptic surgery. Gangrene occurred in the toes and foot as a result of senile changes. The arteries upon the right side of the body were tortuous and exceedingly hard to the touch; on the left side they were soft and apparently normal. The operation was performed with technical antiseptic details. The first dressing remained fifteen days, and when removed union was complete. The patient had since remained in good condition.

Dr. Morris also reported a case of

INJURY OF THE MEDULLA AND SPINAL CORD, WITH AN ACCOUNT OF AN EXPLORATORY OPERATION.

The patient was twenty-seven years of age, who received a severe injury by falling upon the head, attended by almost immediate development of paraplegia below the neck. Diagnosis of fracture of the body of the sixth cervical vertebra, with crushing of the cord, was made. The patient retained the full enjoyment of his intellectual faculties. After giving more extended details of the history of the case and the various clinical phenomena, Dr. Morris gave an account of the details of the operation which he made, with the idea of exsecting the damaged portion of the cord and bringing the divided ends together and fastening them with sutures. The necessary incisions were made under full antiseptic precautions, the spinous processes and the laminæ of the sixth and seventh cervical vertebræ were removed. In this way the cord was exposed, and it was found that its membranes had become united in a firm, dense mass; that the spinal cord itself was very much flattened, not thicker than a sheet of writing-paper; that a few distinct glistening fibres of apparently normal nerve-tissue could be seen passing through this injured part to the parts below, and that the cord below was very much atrophied. The condition of things was such as to preclude any further operative interference, and the wound was closed with full antiseptic details, united by primary union, and the patient was in no way damaged by the procedure. Dr. Morris then gave an account of the symptoms which have developed in the course of the case subsequently.

Dr. C. M. Jones reported a case of fracture of the twelfth dorsal vertebra, and had in his possession the specimen, which illustrated fracture of the laminæ, with pressure upon the cord. The conditions were such as to suggest that if the bone could have been removed by operation, possibly the paralysis might have been relieved. At the time of the occurrence of the injury he suggested such an operation, but it was not accepted by the consultants.

The Chairman had operated in one case of depression of a spinous process in which he found, after removal of the laminæ of one of the vertebræ, extensive extravasation of blood within the spinal canal. The operation gave no relief to the patient, and the case terminated in the usual manner, without recovery of the use of the lower extremities. He thought that operations on the cord for injuries had almost entirely been discarded by surgeons. But the operation contemplated by Dr. Morris was a new field altogether.

Dr. Morris said that in looking up the literature of the subject he had found a large number of cases reported, and all unsuccessful; but he had thought that

the present advantages of obtaining primary union in nerve-tissue and the other soft parts, gave new encouragement to attempt to afford relief by surgical procedure in this class of cases.

Dr. Jacobi spoke of a case on which he operated, some twenty-five or twenty-six years ago, that of a little boy, who received a gunshot wound which was followed by paraplegia. On examination there was a small wound over the second lumbar vertebra. He removed a portion of the body of the vertebra, and found the dura mater very much thickened and very much paler than he had expected to find it; but there was a good deal of organized tissue in that locality, and there it was that he found the bullet, between the bone and the dura mater. He removed the bullet, and also opened the dura mater in order to see the cord, which was found to be flattened and considerably atrophied. The wound healed kindly, but the child died a number of months afterward, in the usual way, and without any improvement following the operation.

Dr. J. C. Peters referred to the oldest and first work on surgery which he ever read, a book written by a French surgeon, who said that almost every part of the body had been invaded by surgical operation, and the author also stated further that, *unfortunately*, the connections of the head with the trunk were such that it could not be removed with the slightest chance of saving the patient's life. The word *unfortunately* Dr. Peters regarded as being very suggestive in connection with the statement made by the author.

The Chairman said that the first case reported by Dr. Morris, that of amputation of the leg, illustrated certainly an advantage which surgeons now possessed, of healing almost any kind of wound. It also illustrated how surgeons now-a-days could perform operations which were essentially curative and not depressing, even under the most unfavorable circumstances, and he believed that some surgical procedures were even more remedial than mercury in syphilis in a large number of cases of chronic diseases.

The Section then adjourned.

The Treatment of Hydrocele.—Dr. T. M. McIntosh, of Thomasville, Ga., writes, in regard to the communication of Dr. Keyes in The Medical Record of February 20th, upon the treatment of hydrocele, that he has in several cases used a somewhat similar, but more simple, method. It consists in the injection of iodine or carbolic acid through a hypodermic needle without previous evacuation of the sac. There are certain cases of encysted hydrocele in which there would be some danger of wounding the testis by the point of the trochar, and other cases in which, owing to thinness of the walls of the sac, and their consequent collapse after the removal of the fluid, great difficulty would be experienced in throwing the fluid into the sac and not into the surrounding tissues. The mode of procedure is to insert the ordinary hypodermic needle, withdrawing just enough fluid to establish the diagnosis; then the barrel of the syringe is disengaged from the needle, filled with the desired quantity of carbolic acid or other injecting fluids, then reattached, when the piston is driven down. It is claimed that there is no pain beyond that caused by the puncture of the needle, and no disability, as the patients are able at once to leave the office and attend to their ordinary duties. It is also, it is claimed, a most effectual mode of treatment. Dr. McIntosh states that the method is not original with him, but that he read about it in a short paragraph in some medical journal about five years ago. The writer had used it for a number of years, and during the war had operated on many cases, the reaction in not a single instance being sufficiently severe to necessitate relief from military duty. In every case a complete cure had been obtained. The material used by the originator of the method was tincture of iodine, from 20 to 40 drops being used for each injection.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GULSTONIAN LECTURES ON SPASM IN CHRONIC NERVE DISEASE—A SANITARY SCANDAL.

London, April 13, 1886.

Dr. Seymour Sharkey's recent Gulstonian Lectures on Spasm in Chronic Nerve Disease contained some pregnant suggestions. Referring to the knee-jerk and allied contractions, Dr. Hughlings Jackson, he said, had formulated the opinion that they are increased in disease which interrupts the continuity of the pyramidal tract, because the suppression of the functions of the pyramidal tract allows increased activity of the spinal centres—the latter being "let go." This explanation was accepted by Dr. Sharkey, and he claimed that partial or complete suppression of nerve-impulses passing from the cerebral motor centres down the pyramidal tract might occur under a considerable variety of circumstances. They might even occur without any tangible lesion being present, for contractures had been observed in typhoid, typhus, and relapsing fevers.

Dr. Sharkey narrated in detail some interesting cases in which tremors, paralysis, and muscular contraction had been produced by pressure on the pyramidal tracts at various points in their course. If the motor tracts of the two sides of the body were affected simultaneously, or soon after one another, the disease was likely to be situated between the basal ganglia above and the medulla below, and was in all probability a tumor.

Rigid contractions and tetanic seizures had been held to be characteristic of cerebellar disease. But as they occurred in disease of other parts of the brain, this could not be so. When occurring in cerebellar disease, they were really due, said Dr. Sharkey, to pressure on the motor-paths, and not to the cerebellar disease *per se*. Dr. Hughlings Jackson, he said, had remarked that in the case of extensive rigidity and tetanus-like seizures occurring in cerebellar tumor, the tumor had been (in his experience) in the middle lobe, and large. Dr. Sharkey said he would put the case thus: "A tumor of the cerebellum does not produce contractures and tetanic seizures, unless it be in such a position and of such a size as to produce pressure on the pons Varolii or medulla oblongata." Dr. Sharkey furthermore said: "I do not think we are justified in considering that disease of it [the cerebellum] produces spasmodic contraction of muscles, except indirectly by pressure upon underlying structures."

Dr. Sharkey regards contractures of cerebral origin as due to injury to the intra-cranial portion of the pyramidal tract, and he pointed out that the results are similar whether the lesion is situated in the motor area of the cortex, in the central ganglia, in the crus, pons, or medulla, provided that the function of the fibres of the pyramidal tract be interrupted. Congenital defects or portions of the central nervous system were, he remarked, as capable as destructive diseases of producing paralysis of limbs accompanied by spasm. Some clinical and post-mortem records were quoted in support of this view.

The lecturer then referred to the various forms of mobile spasm. He admitted that these could not be attributed to any lesion constant either in its nature or its position, but suggested that they result from a mixture, in varying proportions, of paralysis, spasm, and irritation, and that their development depends upon lesions which interfere with the perfect functions of the motor centres and nerves but do not completely interrupt them.

Dr. Sharkey then reiterated a statement which he had made in commencing the course, viz., that "our present knowledge of anatomy, physiology, and pathology does not justify us in concluding that there is any efferent motor connection between the brain and spinal cord,

except the pyramidal tract, direct and crossed, disease of which gives rise to chronic muscular spasm." In making this statement he had wished, he said, to exclude from consideration the cerebellum and central ganglia. Any rigidity or spasmodic contraction of muscles arising in connection with diseases of either the cerebellum or the central ganglia really depended upon involvement of the pyramidal tract, which passed close by them. He had brought forward evidence in support of this view, so far as the cerebellum was concerned. He would now give some evidence of the statement so far as it related to the central ganglia. Dr. Sharkey accordingly related a case in which disease so severe as almost totally to obliterate the corpus striatum, produced hemiplegia, but the latter passed off without leaving rigidity, paralysis, or any other symptom behind. The internal capsule had not been invaded by the lesion.

The lecturer then proceeded to speak of spasm in connection with chronic spinal disease. He observed that the continuous degeneration of the lateral column through the whole length of the spinal cord in cerebral lesions shows that the fibres are not interrupted by entering ganglionic centres, but pass straight to their several destinations in the anterior cornua. It would, he said, be readily understood that if disease destroy them at any level in the spinal cord, degeneration will occur in them below, and produce symptoms of hyper-physiological activity of the spinal centres with which they are connected, similar to those occurring when the disease is intra-cranial. In the latter case, however, all the spinal centres which are under voluntary control are affected, but in the former only a certain number, varying according to the situation of the spinal lesion, whether high up or low down in the cord. Another difference was that in cerebral disease the resulting contracture is, as a rule, unilateral, but bilateral when caused by spinal lesions. The reason of this was that the pyramidal tracts in the spinal cord are so close together as usually to be both involved, whereas, in that portion of the brain where they are most liable to be interrupted by disease, they lie at some distance from each other. The symptoms of disease of the lateral columns of the cord are the same, said Dr. Sharkey, whether it follow cerebral or spinal lesions. The affections of these columns differed slightly according as they are primary or secondary. Disease of the lateral columns might be combined with that of some other tract of fibres, and a combination of symptoms result. Moreover, although pressure on the pyramidal fibres interrupts their functional activity, the symptoms were very different, according to the manner in which the pressure be applied, whether from without or within the cord. A tumor growing in the spinal canal outside the cord might produce few symptoms until it pressed the cord against the walls of the canal, but after this had occurred the course of the disease was rapid. On the other hand, a tumor arising within the spinal cord disturbed its functions even from the commencement, but as the nerve-substance appeared to be elastic, and to allow a good deal of stretching, a tumor might go on growing for a long time before producing striking phenomena either by pushing the cord against the bony walls of the spinal canal or by exhausting the elasticity of the membranes enveloping it. Dr. Sharkey described and explained these various points in detail, and illustrated them by narrating cases.

I referred on a former occasion to the continued existence of a large dust-sifting yard adjoining the filtering beds of a water company at Battersea, as a sanitary scandal. Last year it was proposed to compel the owners of the yard to sell it to the water company; but they opposed this before Parliament, and as this clause had been inserted by the Parliamentary Committee, the Water Company's Bill was thrown out last year in consequence of this opposition. The bill has now again come before Parliament, and it appears that the Water Company and the Railway Company owning the dust yard, have been able to come to an agreement as to the matter, whereby the Railway Company (who are unwilling to part with the ground) undertake to put a stop to the dust-sifting. Meanwhile the nuisance has been going on, although the Local Government Board has issued a report condemning the continued existence of the yard. Public opinion has also not been idle, but in spite of all, we are only now on the verge of settling what would appear—to one unversed in sanitary law—to be a very simple question, viz., the removal of a nuisance which is also a danger to health. I have a very strong suspicion that, despite the present virtuous sanitary stand of the Local Government Board, the nuisance would be as far from being abated as ever, were it not for public and professional opinion.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 18, to April 24, 1886.

TAYLOR, M. K., Major and Surgeon. Granted one month's leave of absence, on surgeon's certificate of disability, with permission to leave the limits of the Department. S. O. 39, Department of the Missouri, April 16, 1886.

GRAY, WILLIAM W., Captain and Assistant Surgeon. Ordered to Fort Maginnis, M. T. S. O. 33, Department of Dakota, April 16, 1886.

WOODRUFF, EZRA, Captain and Assistant Surgeon. Ordered to Fort Missoula, M. T. S. O. 33, Department of Dakota, April 16, 1886.

ROBERTSON, REUBEN L., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Snelling, Minn. S. O. 33, Department of Dakota, April 16, 1886.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 24, 1886.

LOVERING, P. A., Passed Assistant Surgeon. Ordered to Navy Yard, New York.

BIDDLE, CLEMENT, Passed Assistant Surgeon. Detached from Monocacy. Ordered home and wait orders.

AMES, H. E., Passed Assistant Surgeon. Detached from Navy Yard, New York, and ordered to Monocacy.

CRAWFORD, M. H., Passed Assistant Surgeon. Ordered to Naval Hospital at Washington.

Medical Director W. T. HORD, U.S.N., and Medical Inspector J. C. SPEAR, U.S.N., delegates to the American Medical Association, to be held at St. Louis on May 5, 1886.

A LONG CORD, A KNOTTED CORD, AND A LARGE INFANT.—Dr. J. T. Faucett, of Idaville, Tenn., writes to the *Mississippi Valley Medical Monthly*: "I was called to Mrs. F——, February 5th. In about an hour after my arrival she gave birth to a twelve-pound female child. The umbilical cord measured four feet seven inches, and had two perfect knots. Doubtless you have seen longer cords with more knots in them, but this is my longest; and I doubt not but that you have delivered larger children, but this is my largest. In looking over the authorities upon the subject I find that Cazeaux, Leishman, Tyler, Smith, Lusk, and others, give the average length of the cord at from twenty to twenty-four inches. At the same time they all say that instances are on record where the length exceeded the one I report, being five, six, even seven feet in length. The weight of the child, while not sufficient perhaps to excite the wonder of obstetricians, is still quite enough to arouse the astonishment and admiration of a neighborhood."

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 24, 1886 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
April 24, 1886.....	1	7	46	7	25	75	1	0
Deaths.								
April 24, 1886.....	0	4	12	6	4	33	0	0

HYSTERICAL SINGULTUS.—There is a form of hysteria peculiar to the inhabitants of Archangel, in which one of the most prominent symptoms is hiccough (*Russkaya Meditsina*, March 9, 1886). Women are chiefly affected, though the men are not all exempt. The attack begins after some mental excitement, or without such cause, by a sudden intermittent spasm of the diaphragm. The patient cries out, the muscles of the upper extremities contract and relax, the eyes roll, and consciousness seems to be lost. The hiccough continues throughout the attack, which seldom lasts more than half an hour.

SUICIDE BY BUTTING THE HEAD AGAINST A STONE WALL.—Mr. William Allan reports, in the *Dublin Journal of Medical Science* for March, 1886, a case of a prisoner who, on being informed that his wife had just been arrested, started off at full speed toward a wall some fifty feet away, and dashed the vertex of his head against it. So great was the concussion that the body rebounded three feet from the wall, and the man dropped dead without a struggle. The case was of interest from a medico-legal point of view, as if the man had not been seen by witnesses to commit suicide it might reasonably have been supposed that he had been struck by a keeper, or a fellow-convict.

CHLORAL AS A VESICANT.—Hydrate of chloral has, according to the London *Medical Record*, been successfully employed instead of cantharides for blisters. For this purpose powdered chloral is sprinkled on previously slightly warmed adhesive plaster. Vesicles are raised by it in about ten minutes. The advantages of this blister over other kinds are rapid and perfectly painless action, and absence of any of the troublesome effects sometimes caused by cantharides.

ETHER AND OPIUM IN SMALL-POX.—During a recent meeting of the Medical Society of the Paris Hospitals, MM. Dreyfus-Brissac and Balzer mentioned that they had tried M. du Castel's ether-and-opium method of treating small-pox for a considerable time, and had convinced themselves of its efficacy. It consists in subcutaneous injections of ether, a daily dose of from fifteen to twenty centigrammes of opium being administered by the mouth. In severe and confluent cases the papules become abortive, suppuration is diminished, and the general improvement is rapid. M. Balzer prefers administering the ether as well as the opium by the mouth, but M. du Castel considers this less efficacious than the hypodermic method.—*The Lancet.*

EARLY PUBERTY.—A curious case of early puberty was shown by Mr. Bruce Clarke at a recent meeting of the London Pathological Society (*British Medical Journal*). The child was only three years and eight months old, but was three feet eight and a half inches high and weighed sixty-two pounds. There was some down on his cheek, and though there was no hair on the chest or in the armpits, he was as hairy as a man about the pubes and in the perinæum. His penis was as large as a man's, and was noticed to be erect every morning, though the testicles were rather smaller than those of an adult. The pomum Adami was well-developed, and his voice was cracked like that of a boy losing his "childish treble." The development of his brain, however, had not kept pace with the growth of his body, and his mental state was about that of a child of his years. The girth of the head round the occipital and frontal protuberances was twenty-one inches, which is certainly not very small for his bulk. It is interesting to note that, in spite of the great development of his sexual organs, he has never given any evidence of sexual desire, and that no seminal emissions are known to have occurred. The boy was the third child in a family of five, and he was bigger than the eldest child, who was over seven years old. He was suckled for nine months. At about one year of age he began to grow rapidly and to eat voraciously, so that nothing seemed to satisfy him. Hair began to grow on the pubes, and, before he was a year and a half old, he was as hairy as a man. At about that time this very rapid rate of growth ceased, and, since then, his mother thinks he has only grown with ordinary rapidity. A few cases are on record where puberty developed between the ages of two and three years, but Mr. Clarke stated that he had been unable to find any other case recorded where it developed before eighteen months of age.

THE LANDLORDS WHO BLOOM IN THE SPRING.—

The doctor who hunts in the spring, tra la,
For a bright pleasant office up town,
Finds it rather a difficult thing, tra la,
To get a landlord on a string, tra la,
And make his rent figure come down.
And that's what I mean when I say or I sing,
To the devil with landlords who bloom in the spring.
Tra la, tra la, tra la, tra la,
To the devil with landlords in spring.

PERVERSION OF SEXUAL SENSE IN AN EPILEPTIC.—Professor P. J. Kovalevsky reports the case of an epileptic peasant suffering from religious ecstasy and aversion to women, the patient invariably having sexual connections only with animals (at first with hens and ducks, then with cows and mares).

THE OPERATING ROOM OF A VIENNA OPHTHALMOLOGIST.—Dr. G. H. Claiborne, Jr., writing from Vienna to the *Virginia Medical Monthly*, describes the operating room of Professor Hirschberg. "His operating room is a model of scientific care and accuracy. The floor and tables are of marble; the walls are painted with an oily substance which allows of their being washed with soap and water. Glass and porcelain are the materials of which the basins for instruments and disinfecting fluids are composed. The hands of all parties concerned in the operations are washed with soap and water and bathed with a sublimate solution ($\frac{1}{1000}$). The instruments for operations on the ball lie in absolute alcohol; those for muscle and lid operations in a three per cent. carbolic acid solution. Cocaine and atropine are dissolved in $\frac{1}{5000}$ sublimate solutions, and a separate new bottle is used for each case. Professor Hirschberg disinfects the conjunctiva by wiping it carefully with antiseptic gauze wet with a $\frac{1}{5000}$ sublimate solution, and instils one or two pipettefuls of the same solution over the wounds after the operations are finished. He never operates out of this room. Each patient has his own box of solutions, pencils, bandages, etc."

RUSSIAN PHYSICIANS AND THEIR GOVERNMENT.—In Russia medical students are to a very large extent supported and educated by the government, but a pledge is exacted of them to serve in any capacity that may be required, for a certain number of years after qualification. This pledge is felt to be a burden, and a number of medical men, at present under the obligation of serving the government, have petitioned to be absolved from it.

THE INEQUALITY OF THE UPPER EXTREMITIES AND THE CAUSE OF LEFT-HANDEDNESS.—DR. Charles A. Bacon, of this city, writes: "Yours of the 19th inst. received. The extract from the *British Medical Journal*, given on pages 262–63 of THE MEDICAL RECORD for February 27th, recalled to my mind Hyrtl's views on that subject, a translation of which I append. § LXXIV. 'Inequality of the two Upper Extremities. The two upper extremities are very seldom of equal length. There is a difference of two to three lines in favor of the right. Laurent Vitry and Noble found the right clavicle and humerus four lines longer than the left. . . . Moreover, the strength, which means the muscular development, of the two is very seldom in exact correspondence. An original dissimilarity in the mass of muscular tissue in favor of the right upper extremity, and not its more intense use, gives to it its greater importance. We use the right upper extremity more than the left, because it is stronger; it is not stronger because more used. . . . The mass of muscular tissue on the right side is greater than that of the left in the proportion of 1 to 0.929 . . . a difference of more than seven per cent. That the predominating use of the right hand is based on this numerical proportion, is best appreciated on observation of left-handed persons. Such a person's left upper extremity is by natural construction stronger, and, for this reason, he makes use of it from babyhood in spite of correction and punishment, and although all tools and implements are so constructed as to favor the convenient use of the right hand. . . . § LXXV. Anatomical Cause of Left-Handedness. The stronger development of the right upper extremity, and its consequent greater availibility for use, depend upon purely anatomical considerations, just as does left-handedness. They lie in the results of the place of origin of the arterial branches of the arch of the aorta. The right subclavian is given off nearer the heart than the left. The power of the heart's systole will have a greater influence on it than on the left. The right subclavian, as well as all its branches, will necessarily have a greater capacity than the left, because the blood in it circulates under a greater pressure. More blood in it means so much more nutritive material, and also so much more tissue change, and stronger development of all belonging to the upper extremity. That this stronger development should manifest itself in the muscles is to be expected, since the bulk of the extremities is composed of muscle. Our attention is here claimed by an anomaly in the origin of the great blood-vessels, in accordance with which the right subclavian arises behind the left. Nor is it so very rare; I put it at two per cent. This proportion corresponds with the experience of many years in the dissecting-rooms of Vienna, and approximately with Malgaigne's observations on the frequency of left-handedness. If the right subclavian takes its origin behind the left, then, as regards the pressure under which the blood circulates in the two subclavian arteries, we find the opposite from what must occur when the origin is normal. In blood-supply the left extremity has the preference. Consequently it will be stronger and in use preferred to the right. Dr. Oehl, of Pavia, first communicated to me the cases of two left-handed men, in whom the anatomical examination demonstrated the misplacement of the origin of the right subclavian behind the left. Two other recently observed cases establish beyond doubt the causal and necessary relation of anomalies in the blood-vessels to left-handedness. A body with complete transposition of the viscera came into our hands in the anatomical department. The left upper extremity was not noticeably stronger than the right (just as the right is not always perceptibly the stronger); but callosities on the left hand showed that the man—a carpenter—had been accustomed to use his plane in that hand. Almost at the same time I learned that a man—by trade a locksmith—was under treatment in Professor Oppolzer's clinic. On being questioned he asserted, as I expected he would, that from babyhood he used his left hand for everything, until in his fifteenth year his master compelled him to use the right; still, that even now, when he wants to do his best, his left hand is more serviceable than his right. The anatomical cause of left-handedness is consequently no longer a riddle.' The above is a translation of passages occurring on pages 304, 305, 306 of vol. ii. of Hyrtl's 'Handbook of Topographical Anatomy,' sixth edition, published at Vienna by William Braumueller, and is substantially what I heard Professor Hyrtl state in one of his lectures. Being not quite certain as to the solution of 'the riddle,' I spoke with him about it afterward, and I believe it would be correct to thus formulate that great anatomist's answer: Any original abnormal distribution or arrangement of the great arteries causing greater blood-pressure, beginning during fœtal life, in the left than in the right subclavian, is competent to cause increased calibre of the left subclavian, a more copious blood-supply to the left arm, a consequent superiority in its muscular development and left-handedness; and such is always the cause of original left-handedness."

NEWSPAPER ADVERTISEMENTS.—A correspondent, "L. J. B.," writes: "It is stated that when a clergyman raised his prayer-book to throw it at the liar in his congregation every one present dodged their heads. Now, as one of the dodgers, I wish to question a statement made in the recent editorial on 'Newspaper Advertisements.' I cannot vouch for the state of things in New York, but in smaller towns everyone assumes the mantle of reporter, and considers it a privilege to report current events to the newspaper. Thus a man's neighbors—friends or enemies, for that matter—are constantly striving to be the first to announce such events at the paper offices, particularly if something extraordinary to them. Thus, if Dr. so and so performs an operation, not wonderful to himself or the profession, but wonderful to the public, it soon reaches the papers without the knowledge or intent of the operator." [Our correspondent further asks us why we have singled out a certain town of which to make an example. To which we answer that we have not singled out any town or man, but during the past years have made such criticisms as we deemed needful and right, no matter what was the locality. A small proportion of newspaper advertising is inadvertent and accidental, and this proportion is very much smaller than our correspondent appears to think.—ED.]

A CURIOUS DEFENCE.—Dr. Peyrol, head surgeon at the Hôtel Dieu, was called upon to extract a bullet from a young lady who had accidentally shot herself, and made a charge of eight hundred francs for the operation. The bill was disputed, and the case was brought before the Paris Civil Tribunal. Here the defence was set up that the plaintiff had stated erroneously that the bullet was lodged in the right thigh. But the tribunal very justly overruled the plea, saying that it mattered very little whether the bullet was on the right or left side, so long as the patient's sufferings had been relieved, and judgment was accordingly given for the plaintiff.

A TRUSS WITH A GLYCERINE PAD.—A truss is manufactured in England, which has a pad made of india-rubber and filled with glycerine. It has been found that the glycerine does not evaporate or leak through the rubber, and the pad always remains soft and comfortable. The latter has sufficient resistance to overcome the ordinary forms of hernia, and, from its peculiar construction, adapts itself well to the surface, and completely closes the external ring without enlarging it.

THE DIET IN DIABETES.—*Articles permitted:* Almonds, plain, in rusks and in biscuits, bread toasted or stale maccaroni, bacon, butter, cheese, eggs, fat and oils, beef-tea and soups, beef, mutton, fish, game, and poultry, cabbage, lettuce, pickles, and spinach, custards without sugar, cream, jellies unsweetened, nuts; coffee, cocoa, sherry. *Articles forbidden:* Peas, beans, lentils, pota-

toes, sweet potatoes, celery, carrots, beets, radishes, mustard, oysters, arrow-root, buckwheat, sago, tapioca, and puddings generally, apples, bananas, and fruits generally, including raisins; milk, sugar, chocolate, ale, sweet wines. —*Journal of Reconstructives.*

The Digestibility of Various Kinds of Foods According to Vanderbeck. *Meats.*—Easy to digest: Mutton, venison, hare, sweetbread, chicken, turkey, partridge, pheasant, grouse, beef. Hard to digest: Pork, veal, goose, liver, heart, brain, lamb, duck, salt meat, sausage. *Fish.*—Easy: Turbot, haddock, flounder, sole, oysters, trout, pike. Hard: Mackerel, eels, salmon, herring, salt fish, lobster, crabs, mussels, cod. *Vegetables.* —Easy: Asparagus, French beans, cauliflower, beets, potatoes, lettuce. Hard: Artichoke, celery, spinach, boiled cabbage. *Fruits, etc.*—Easy: Baked apples, oranges, grapes, strawberries, peaches, cocoa, coffee, black tea, claret. Hard: Apples, currants, raspberries, apricots, pears, plums, cherries, pineapples, chocolate, pickles, beer.—*Journal of Reconstructives.*

The Comparative Cost of Foods.—Oatmeal is one of the cheapest foods we have; that is, it furnishes more nutritive material, in proportion to the cost, than almost any other. Wheat-bread and rice, on the other hand, are the most expensive, in proportion to their cost, of the staple vegetable foods. By taking into account all the nutritive substances, it is estimated that twenty-five cents will pay for 0.29 of a pound of nutrients in beef sirloin, 0.40 in round beef, and 0.92 in neck beef; oysters, 0.12 to 0.17; shad and bluefish, about 0.28; smoked-herring, 1.21; cheese, 1.08 to 1.35; milk, 0.99; wheat-bread, 2.08 to 2.75, etc. Of course, in the comparative value of foods, their actual physiological use is not unimportant. Foods rich in nutrients may not be readily assimilable, and only physiological experiments can finally determine their actual nutritive value. From a study of the dietaries of factory and mill operatives, mechanics, and other people engaged in manual labor in Massachusetts and Connecticut, the most noticeable features observed were the large quantity of food consumed, especially of animal food and fats. The total amount of nutrients per man per day varies in the Massachusetts dietaries from 690 grammes to 1,052 grammes; while in the European dietaries the normal range is from 653 to 863 grammes. In the European the consumption of fats ranges from 13 to 100 grammes, while in the Massachusetts dietaries in no case does it fall below 127, and reaches as high as 304 grammes. If common usage in Europe, and the standards which are currently accepted there, are correct expressions of the proper quantities of food and of fat for healthful nutrition, the quantities of total food, of meats, and especially of fats, in the New England dietaries examined, are needlessly large, and in some instances excessively so. The dietaries studied, all pointed in one direction, indicating that in this country a large excess of food is consumed, not only by well-to-do people, but also by those in moderate circumstances. This excess consists mainly in meats and sweetmeats, which are expensive, as well as physiologically injurious when consumed in too large quantities.—*Science.*

Artificial Cocaine.—Merck is said to have prepared cocaine by synthesis. Cocaine is benzoic methylecgonine. Benzoic ecgonine is treated with iodide of methyl in slight excess, in the presence of methylic alcohol at 100° C.; the excess of iodide and methylic alcohol is driven off by heat; from the resulting syrupy liquid cocaine is extracted. This artificial cocaine melts at 98°, like its prototype, and it possesses all the reactions of the natural product.

The Results of Treatment in Diphtheria.—Dr. Wooster Beach, of this city, takes exception to a statement made in a paper on "Diphtheria and its Treatment," concerning the mortality of the disease, which is stated, on the authority of the statistics of the Health Department, to be over forty-two per cent., and which was reduced by treatment in the cases described to about fifteen per cent. Dr. Beach writes: "Now, without attempting to prove the fact by statistics, I state very confidently, first, that not one case in ten, except it be fatal, is reported to the Health Department; and, second, that the average mortality from the disease in this city does not reach fifteen per cent." Allowing for cases of tonsillitis, diagnosticated as diphtheria, and for other errors in diagnosis, the writer expresses his confidence that practising physicians will sustain him in his estimate of the mortality of true diphtheria, although when the larynx is invaded the death-rate is enormously increased. He says that he has tried many of the plans advocated by reliable authorities, and that now his treatment of the disease is practically nil, yet he sees very little difference in the results obtained. "Dr. Smith's percentage of cures does not, then, exceed that following ordinary treatment, and this leads me to the object of my communication: to protest against this harassing, I might say, torturing, of the little patients by the almost continual syringing, spraying, and dosing. I cannot better illustrate this point than by extracts from the article. One 'little patient was very intractable, so that I was never able to satisfactorily syringe out his nose and throat.' Another 'required the united efforts of my assistant, nurse, and father of the patient to hold him in a chair while I syringed out his throat and nostrils.' I have had personal experience in such scenes, and firmly believe that the baneful effects of the fright, excitement, and exhaustion must counterbalance any advantage of the treatment, allowing it to be of service at all. Two cases of death immediately following, and not improbably caused by violent resistance to the syringing process have come to my knowledge. I hold that in this disease, in fact in all others, remedies or measures that may do harm should never be employed unless the evidence of their superiority over more innocuous means can be fully sustained."

Primary Carcinoma of the Omentum.—Dr. E. D. Coonley, of Mariner's Harbor, writes: "With reference to a statement made by Dr. Ferguson at a recent meeting of the New York Pathological Society, that he had never seen a case of primary carcinoma of the omentum, and that they were exceedingly rare, I would like to quote the following from notes of an autopsy made by me in October, 1883: The great omentum was the seat of large cancerous deposit; was greatly thickened and increased in weight. The kidneys were not examined, but were probably normal, judging from the character of the urine examined a few hours before death. The spleen, stomach, and liver were perfectly normal."

A Large Fibroid Tumor.—Dr. Atherton, on October 22d last, removed a fibroid tumor of the uterus weighing about sixty pounds. The patient was thirty-five years of age, and the tumor first showed itself immediately after marriage, twelve years ago. Its seat of growth was in the anterior wall of the uterus and was firmly adherent to the abdominal wall, evidently receiving a large part of its blood-supply through the enlarged branches of the epigastric arteries. The patient has gained twenty-eight pounds since the operation.—*Canada Medical and Surgical Journal,* March, 1886.

The Need of a Law to Regulate the Practice of Medicine in Maryland is apparent from the following certificate of death of a bride of two months. The document was filed with the Health Department after having been used as a subscription paper to collect funds to enable the remains to be buried. It was given by Dr. Johnson, a colored herb doctor, of Stockholm Street, and read as follows: "March 3, 1886.—Mrs. Larro Jones, she dide with Liver dease & New Moner she daparted from this life & Mat with chance to Make her leafe & got to glory. We ask freands & Brother & Sister for what they Can give to halpe to Bary the body away."

THE MALARIAL "GERM" OF LAVERAN.

BY GEORGE M. STERNBERG, M.D.,

MAJOR, U.S.A.

(Continued from p. 453.)

IN a plate accompanying the recent memoir of Marchiafava and Celli,[1] these crescentic bodies are figured, not as attached accidentally to red blood-corpuscles, but as developed in them, and as being a later stage in the development of body No. 2, shortly to be described. We cannot attempt to reproduce the excellent lithographic plate which illustrates the various phases in the development of the parasite, as interpreted by these observers, and must content ourselves with the remark that according to them the crescentic bodies are developed from body No. 2 in the interior of the red blood-corpuscles, and simply represent a more advanced stage in the evolution of these bodies at a time when the corpuscle has been nearly (as in B, Fig. 3) or entirely destroyed. Subsequently the crescentic body, according to these observers, becomes oval, and then spherical in form. Whether the life-history of the parasite has been correctly worked out by the Italian observers is a question which we cannot attempt to decide. However, the exact relation which this body No. 1 of Laveran bears to body No. 2 is a question of secondary importance, which we may leave for future investigation. The main interest, from an etiological point of view, attaches to body No. 2, *which is found in the interior of the red blood-corpuscles*, and which corresponds with the hyaline bodies found in such vast numbers, in the same situation, in the capillaries of the brain, liver, spleen, and other organs, in fatal cases and pernicious malarial fever.

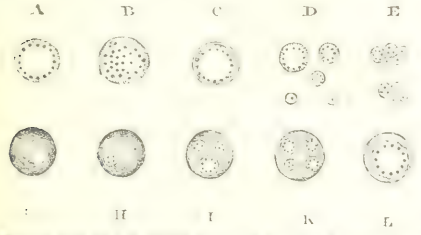

FIG. 4.—A, body No. 2 of Fig. 3, volume B, body No. 1, containing pigment granules; C, body No. 2, containing pigment granules; D, body No. 2, containing pigment granules; H, body No. 2, containing pigment granules; I, body No. 2, containing pigment granules; K, body No. 2 of small size to the number of one, two, three and four; L, a red blood-corpuscle, to which are attached body No. 2 and crescentic body. (Magnified about 1000 diameters.)

This body No. 2 is described by Laveran as follows:

"These elements are without question the ones most frequently encountered in the blood of malarial patients. Fig. 4 shows the principal aspects under which they present themselves to the observer. Their form is spherical; but we will see further on that this form may be modified under the influence of movements comparable to amœboid movements.

"The dimensions vary considerably; the smallest of these bodies are scarcely one micromillimetre in diameter, the largest may have a diameter of ten to eleven micromillimetres.

"The contours are indicated by a very fine line, and we may sometimes distinguish a double contour (C, Fig. 4), especially in preparations treated with osmic acid, colored with picrocarmine and mounted in glycerine.

"These elements appear to be made up of a very transparent hyaline mass enclosing rounded granules of pigment of a black, or deep-red color, identical with that found in bodies No. 1. The smallest of these bodies often enclose only one or two granules of pigment (D, Fig. 4); in the bodies which have a greater volume the pigment grains are often disposed regularly in the form of a crown (A, C, Fig. 4), or they may be distributed without order (B, Fig. 4), and in this case are animated with active movements comparable to particles of solids in a liquid in ebullition. This agitation of the pigment granules has a certain resemblance to the Brownian movement, but has not the regularity of this latter; sometimes the movement is arrested completely, sometimes it is exaggerated without any change having occurred in the physical condition of the preparation. *A priori* one would be tempted to believe that the pigment granules are animated by a movement proper to themselves; we will see further on, in studying the mobile filaments, that the movement is probably communicated. The pigment granules are immobile in the bodies No. 2 of small volume, while in those of average dimensions and of large size they may almost always be seen to move at certain times, especially in a preparation maintained at a temperature sufficiently elevated.

"These spherical bodies are sometimes free in the serum, sometimes attached to the red blood-corpuscles (H, I, K, L, Fig. 4). The bodies of small size free in the serum are often united in groups of four, five, six, or more (E, Fig. 4). The spherical bodies attached to the blood-corpuscles have a variable size; sometimes there is but a single body of small dimensions, enclosing one, two, or three granules of pigment, or there may be two, three, or four such bodies attached to the same corpuscle (H, I, K, Fig. 4); sometimes these bodies are more voluminous and have a diameter almost equal to that of the diameter of the corpuscle, which becomes more and more pale, and is only recognized by a zone of a pale yellow color surrounding the parasite. A moment finally arrives when the corpuscle can no longer be distinguished except by its contour; its color has disappeared; its transparency is the same as that of the parasite which is attached to it. This last body then appears to be surrounded by a transparent zone, which is more or less concentric to it; soon the corpuscle disappears entirely, and in proportion as it is effaced the body No. 2 augments in volume.

"We find often in preparations of the blood of malarial cases red blood-corpuscles which present little clear spots which might be designated under the name of *hématies piquées* (G, Fig. 4). It is probable that these clear spots are produced by the spherical bodies just born, so to speak, which do not yet contain pigment. MM. Marchiafava and Celli[1] seem to have observed this phase of the alteration which occurs in the blood of malarial cases.

"Certain bodies No. 2 enclosing pigment granules have exactly the diameter of the red corpuscles; we may, therefore, ask whether we have to do with parasitic

[1] Trans. R. Acad. Lincei, 1884.

[1] Gazz. degli Ospitali, 1883, No. 66.

elements having an independent existence, or with corpuscles altered by the presence of parasites which have penetrated into the interior of the corpuscles, as weevils penetrate grains of wheat. This hypothesis and this comparison have been made by Richard.[1]

"Besides these bodies No. 2 which have nearly the diameter of the red corpuscles, there are others which are only one or two micromillimetres in diameter, and which are consequently smaller than the smallest blood-corpuscles in diameter; the existence in the blood of bodies No. 2 of small size, free, and independent of the corpuscles, shows that these bodies have a proper existence; besides, a blood-corpuscle which has no envelope, properly so called, and of which the elasticity is so great that it yields to the slightest pressure, cannot be compared to a grain of wheat.

"Richard himself has abandoned the hypothesis which he had proposed. In his last communication upon the microbes of paludism he expresses himself as follows: 'These bodies are sometimes isolated, sometimes attached to each other in twos, in threes, or even in fours. But much more frequently, in place of swimming freely in the plasma they are attached—*accolés*—to the red corpuscles, at the expense of which they are nourished. Sometimes the corpuscle with its parasite preserves its discoid form, more often it assumes the shape of a cap and embraces the microbe by its concavity. One might then believe that the parasite is included in the corpuscle itself, and I have thought for a long time that this is the case; to-day I am persuaded to the contrary.'"[2]

The writer has heretofore spoken of these bodies as being "in the interior" of the red blood-corpuscles; this was the impression I obtained when they were demonstrated to me by the Italian observers heretofore named, and is an inference resulting from their supposed identity with the hyaline bodies, which appear to be included in the red corpuscles, in the capillary vessels of the brain, etc., in fatal cases of "pernicious fever." This is also the view of Marchiafava and Celli, who have made extensive observations during the past summer in the Santo Spirito Hospital of Rome,[3] where the material for such studies is most ample. Moreover, the stained preparations made by these gentlemen from blood drawn from the finger of a malarial patient, in my presence, seemed to justify this inference. But in view of the different opinion held by Laveran and by Richard I am not disposed to consider the point as definitely settled, and would commend it to the special attention of future observers.

In Laveran's account of his body No. 2, as above quoted, he remarks that "their form is spherical; but we shall see further on that this form may be modified under the influence of movements comparable to *amœboid movements*."

This phenomenon, referred to by Laveran, has been repeatedly observed by Marchiafava and Celli, and was demonstrated to me during my recent visit to Rome. Passing through the Santo Spirito Hospital, Dr. Celli selected a case in which the initial symptoms of a malarial paroxysm were developed, and drew a little blood from the patient's finger in the manner recommended by Laveran. This was immediately placed under the microscope, and after a little search a red blood-corpuscle was found which, *apparently, contained* a refractive spherical body, corresponding in size and location with the hyaline bodies which I had often seen in Councilman's sections of brain, etc., from the two cases of pernicious fever described by him. I would have been unable to determine whether this body was in truth a living organism by its appearance alone, but watching it for a time I had the most unequivocal evidence that such was the case. I observed, first, that, after a period of quiescence, a minute bud was put out from one side of the spherical body; this was the commencement of a change in form, amœboid in character, which continued for some time, and during which the body under observation assumed a variety of shapes, as shown in Fig. 5, which is copied

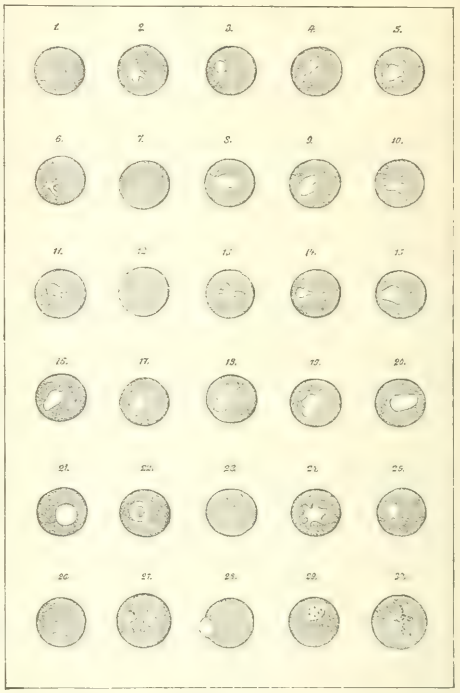

FIG. 5.—Figures 1 to 22 represent the changes in form which a single plasmodium, included in a red blood corpuscle, was observed to undergo within a period of twenty minutes. Figures 23 to 27, 29, and 30 show other forms assumed by plasmodia, some with and some without pigment. Figure 28 shows a motionless plasmodium emerging from a red blood-corpuscle; the blood was taken after the paroxysm of fever and administration of quinine. (Copied from the latest paper by Marchiafava and Celli, published in Friedlander's Fortschritt der Medicin, December 15, 1885.)

from the paper of Marchiafava and Celli, heretofore referred to. This I saw repeated not in one corpuscle only but in several, and had thus an ocular demonstration that these bodies are living amœboid organisms. The motions were quite slow, and were manifested by a gradual change of outline rather than by visible movement. After a period of amœboid activity of greater or less duration the body again assumed an oval or spherical form and remained quiescent for a time. While in this form it was easily recognized, as the spherical shape caused the light passing through it to be refracted and gave the impression of a body having a dark contour and a central vacuole; but when it was flattened out and undergoing amœboid changes in form, it was necessary to focus very carefully and to have a good illumination in order to see it. The objective used was a Zeiss' one-twelfth inch hom. ol. im.

We find further reference to this amœboid movement in Laveran's work (p. 168):

"When one examines these bodies No. 2 of average dimensions, or of large size, at a temperature of 30° to 35° C., one may often see that they undergo changes of form, while the pigment-granules in their interior are agitated in a very lively manner; these changes, which are produced slowly, as in the amœbæ, are easy to verify when the same element is left for a considerable time in the field of the microscope, and when a drawing is made, every five minutes for example. Little buds of proto-

[1] Communication to the Academy of Sciences, [illegible], 1885.
[2] Revue Scientifique, 1885, p. 111.
[3] Since this paper was written I have received from Marchiafava and Celli, a reprint of their last communication, published in the Fortschritte der Medicin, No. 24, December, 15, 1885. This paper embodies the results of their researches during the past summer, which are confirmatory to those previously published.

plasm are sometimes formed upon the margin of body No. 2.

"When body No. 2 is examined attentively, it happens sometimes that we see it undergo segmentation into three or four similar elements of small volume; these elements may again coalesce to form a single body, resembling in all particulars the primitive body No. 2."

Marchiafava and Celli have also observed this segmentation, and believe that it represents an important phase in the life-history of the parasite, and, in fact, that it is the usual method by which it multiplies. They have found evidence of segmentation also in the hyaline bodies included in the red blood-corpuscles in some of their sections of brain-tissue from cases of pernicious fever. I have in my possession a preparation, which they kindly gave me, in which the hyaline bodies (Laveran's bodies No. 2) are deeply stained with visuvine, and in which groups of two to six or eight small spherical bodies are to be seen included in the red corpuscles, which it seems probable may have been developed as a result of the segmentation of the larger bodies.

Continuing to quote from Laveran, we find the following:

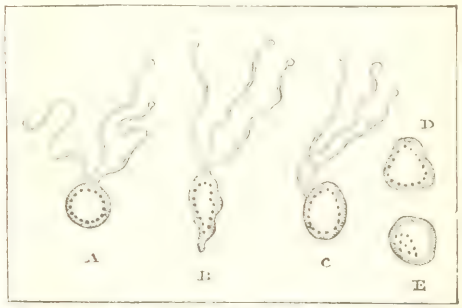
"*Mobile filaments.*—When a preparation of blood containing the spherical bodies described is examined attentively, it often happens that upon the margins of some of these elements we may distinguish filaments which are in active movement, and which impart to the neighboring blood-corpuscles very rapid and varied movements. These mobile filaments, of which the vital activity is incontestable, appear to represent the adult state of the malarial microbe; their study, then, is of great importance, but, unfortunately, is attended with considerable difficulties. The mobile filaments are very long for microbes, as they are at least three or four times as long as the diameter of a red blood-corpuscle, that is to say, twenty-one to twenty-eight micromillimetres long. But their tenuity and their transparence is such that when they are in repose one does not see them. It is thus that in repose the vibratile cilia of certain infusoria are invisible. It is well known that a glass rod plunged in Canada balsam becomes invisible, the index of refraction of the glass being nearly the same as that of the balsam. Still more difficulty attends the detection of very fine and transparent filaments in a state of repose in the serum of the blood.

"The movements of these mobile filaments are often arrested for a time when the blood has been collected upon a glass slide, especially if the exterior temperature is low, and if one does not make use of a hot stage. I have several times remarked at Constantine, during the summer, when the external temperature is quite elevated, that the movements of these filaments may be observed at the commencement of the examination of the blood; while in winter, when the temperature of the laboratory was low, it was often necessary to wait a long time in order to see the mobile filaments. We note, finally, that those mobile filaments correspond to a certain stage in the evolution of the malarial parasite, and that consequently we should not expect to find them permanently," *i.e.*, at all times, "in the blood of malarial patients.

"For these different reasons the search for these filaments is quite difficult, and it will be understood how it has happened that these microbes, notwithstanding their length and the vivacity of their movements, have so long escaped the attention of observers.

"Sometimes these mobile filaments are free in the midst of the blood-corpuscles, sometimes they adhere by one of their extremities to the spherical bodies No. 2. The free filaments move in the midst of the red corpuscles like an eel, and it is difficult to follow them; the filaments which still adhere to the bodies No. 2 are more easy to study, because they move vigorously without change of location and remain in the field of the microscope. . . .

"Dr. Richard has given an excellent description of the varied movements presented by these mobile filaments; he says: 'These filaments are animated by extremely active and energetic movements, by which the neighboring blood-corpuscles may be deformed or even displaced. From time to time the movement relaxes, to take the same activity after an interval of some instants; when they encounter some obstacle which interferes with their evolution the filaments redouble their activity; to see these movements one would almost say that they have an intentional character: thus one day it happened to me to observe a filament wrapped around a mesh of fibrinous reticulum, immediately its activity increased, it was agitated by veritable jerks, by movements of impatience, if I dare express myself thus, as if it sought to disengage itself. These little dramas in the field of the microscope are varied and often very attractive."



. . . "The movements of the mobile filaments may persist for two or three hours, in general they cease in much less time. When pressure is made upon the cover-glass in such a way as to act mechanically upon one of these bodies No. 2 furnished with mobile filaments, the motions are almost always arrested. When one examines one of these spherical bodies furnished with filaments, the first idea which presents itself is that the object in view is a pigmented mass of spherical form having pseudopodia. Such was the first hypothesis which I made with reference to the structure of these bodies; a more attentive examination soon showed me that it was necessary to abandon this interpretation. In the first place, it is often impossible to discover any mobile filaments upon the margin of the bodies No. 2, even when they have attained their average dimensions; in the second place, the number of the mobile filaments is variable; finally, when we examine for some time one of these bodies No. 2 furnished with mobile filaments, it will be found almost always that in the end these filaments are detached from the body No. 2, in which they had been inserted; these filaments circulate then at liberty in the midst of the red corpuscles, while the body No. 2, like a cyst which has been emptied, remains motionless and soon becomes deformed. The spherical bodies are probably little cysts, in the interior of which the mobile filaments are developed; it has happened to me several times to see the mobile filaments which had only partially escaped from body No. 2, and which during the examination completed the process of liberating themselves from their cyst. . . . Dr. Richard has also verified the fact that the mobile filaments adherent to body No. 2 often become detached from these bodies. He says: 'The filaments often take an independent existence; they become detached from the mother-element, and then, with prodigious agility, they precipitate themselves like little serpents through the pile of red corpuscles, and it is very difficult to follow them for a long time on account of the

rapidity and extent of their movements. In those cases in which these filaments are numerous the blood appears to be literally living.' "[1]

Marchiafava and Celli have also seen these mobile filaments attached to body No. 2. Their observations and figures indicate that they are flagelliform pseudopodia, which are developed during a certain phase in the evolution of this remarkable micro-organism, rather than independent bodies set free from a cyst. Whatever may be the truth in this regard, it can hardly be questioned that the flagellate bodies containing pigment granules, which have been seen by all of the observers mentioned in the blood of patients suffering from malarial fever, are derived from the far more numerous bodies No. 2 of Laveran, and constitute one stage in the development of this blood-parasite; and that the free mobile filaments described by Laveran and by Richard are detached from these bodies under certain circumstances, and may for a time retain their vital activity independently of them.

Laveran describes a third form, "body No. 3," which he considers a "cadaveric form" of the parasite. He says: "These elements are composed of little masses of hyaline material enclosing pigment-granules, disposed in various ways. . . . It is easy to satisfy one's self that these elements are only the cadaveric forms of bodies No. 1 and No. 2. When we leave under the microscope a preparation containing bodies No. 1 and No. 2, and examine them at the end of twenty-four or forty-eight hours, it will nearly always be found that these elements are distorted—*se sont déformés*—and that they have taken the aspect of the bodies No. 3. . . . In the bodies of individuals dead from malarial fever bodies No. 1 and No. 2 rapidly take the aspect of body No. 3; it is in this condition that the parasitic elements are found in great number in the small vessels of the various organs in subjects dead from pernicious fever, notably in the spleen, in the liver, and in the brain; these are the elements which, when agglomerated in masses, constitute the hyaline concretions which Frerichs has very well observed and described."

Laveran, in his first communication, gave to the blood-parasite, which he had discovered, and which he believed to be the cause of the disease with which, according to his observations, it is constantly associated, the name of *oscillaria malariæ*. He has since abandoned this name, which had been criticised, and says in his recent work, from which we have already quoted so extensively: "I renounce this name the more willingly for the reason that the *oscillariæ* are to-day classed among the vegetables, while the malarial parasite appears to me to belong to the animal kingdom rather than to the vegetable." The account above given fully sustains this view, and it is evident that this organism does not belong to the *bacteria*, the class which includes the spirillum of Obermeier, the tubercle bacillus, and other known "disease germs," but is rather one of the *protista*, which, according to Haeckel's classification, includes a large number of the lowest forms of life, which are neither distinctly animals nor vegetables, but form "a kingdom of organic nature intermediate between these two." Marchiafava and Celli, in their latest paper (*loc. cit.*), propose to call this organism *Plasmodium malariæ*.

The etiological relation of this amœboid blood-parasite to the form of disease with which it is associated can scarcely be questioned, if additional researches sustain the conclusion of the observers heretofore quoted as to its constant presence in the blood in typical cases of malarial fever, and its absence from the blood of healthy persons or of those suffering from other forms of disease. The idea that a parasite of this kind, which attacks directly the blood-corpuscles, and which in fatal cases of pernicious fever is found in vast numbers in the interior of these essential histological elements of the blood—or, according to Laveran, attached to them—is to be considered a mere epiphenomenon, until such time as its causal relation to the morbid phenomena has been proved by inoculating lower animals with pure cultures, can scarcely be entertained in the present stage of scientific investigation in this direction. We have no satisfactory evidence that the lower animals are subject to malarial diseases, and this final proof, however desirable, may be unattainable. We have, however, some recent inoculation experiments upon man, which give some support to the view that this parasite is the essential cause of the periodic fevers denominated malarial.

Marchiafava and Celli have, in five cases, made the direct experiment of injecting blood drawn from the circulation of a malarial patient, and demonstrated by microscopical examination to contain the parasite heretofore described, into the veins of individuals free from malarial disease, and from exposure to malarial influences (?), and claim that typical attacks of intermittent fever have resulted from such injections. The temperature charts given sustain this claim in three of the five cases, and the only doubt which arises as to the value of the experiment is that which is based upon the possibility of an attack developed as a result of exposure to malarious influences from without rather than from the injections made. The circumstances, as detailed, and the number of cases subjected to the experiment (five) seem to exclude this source of error; but additional experimental evidence from other sources will be necessary before we can admit that intermittent fever is an infectious disease transmissible from individual to individual by intravenous injection of the blood of one suffering from a malarial attack.

We select Case 3 as the most characteristic of those given in the memoir[1] of the authors referred to.

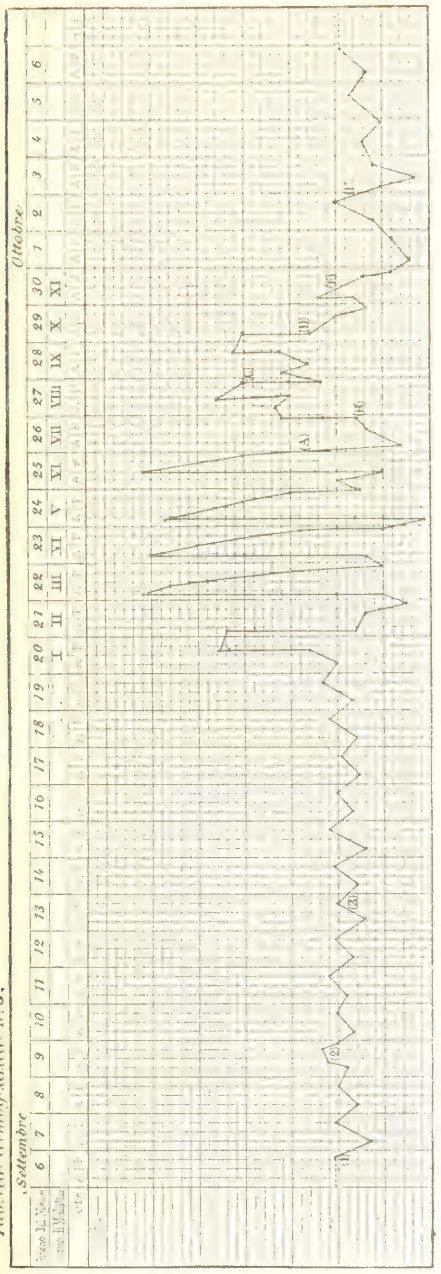
The subject of the experiment, M. C——, was a patient in the hospital of Santo Spirito, aged thirty-two, under treatment for multiple sclerosis. He had never suffered from malarial fever, and his temperature, taken for several days in advance of the experiment, showed no abnormal elevation. On September 6th, one gramme of blood from a patient in the cold stage of an intermittent attack—quotidian—was injected subcutaneously. Three days after, an intravenous injection was made of one gramme of blood taken from a patient in the hot stage of a quotidian intermittent attack. These injections were not followed by any immediate rise of temperature, or other noticeable effects. A third intravenous injection of one gramme of blood from a patient with malarial cachexia, and irregular febrile attacks, was made September 13th.

No elevation of temperature occurred during the seven days following this third injection, but on the afternoon of September 20th, a sharp access of fever occurred, as shown in the accompanying temperature chart. Defervescence took place the following morning, with abundant perspiration. This was followed on the 22d by another paroxysm, in which the temperature quickly rose to 41.2° C. (106.2° F.), and by other characteristic paroxysms occurring on three successive days. The administration of quinine was commenced on the 27th (45 grains), and continued as indicated by the letters in the chart: A, 3 grammes; B, 2 grammes; C, 2 grammes; D, 1.50 gramme; E, 1.20 gramme; F, 1 gramme. The spleen was notably enlarged during the attack and the case bears every evidence of having been a typical one of quotidian intermittent fever. Examination of the blood, repeated every day, demonstrated the presence of pigmented leucocytes and of the "initial form" of the parasite. Both disappeared under the administration of quinine. Two other cases similar to this are reported, and in one (Case 1) the remark is made that the microscopic examination of the blood fully confirmed the diagnosis as to the malarial nature of the fever, the parasite having been found in the red cor-

[1] Revue Scientifique, 1883, p. 11[illegible]

[1] Nuove ricerche, etc., [illegible]

puscles, at first in small numbers, and subsequently in great abundance, and having disappeared after the administration of full doses of quinine, by which the febrile paroxysms were arrested.



The authors quoted refer to two cases reported by Gerhardt,[1] in which a similar result was obtained by inoculations, in man, with malarial blood. The period of incubation in these cases is said to have been seven and twelve days. They remark that in their own experiments it is difficult to fix the period of incubation, owing to the fact that several successive inoculations were made in each case.

Laveran finds an additional argument in favor of the etiological rôle of the parasite discovered by him in the curative action of quinine. According to his observations, the parasite quickly disappears from the blood under the administration of quinine, and in this he is also confirmed by Marchiafava and Celli. In experiments made with blood drawn from the veins of a malarial patient which was rich in the parasitic elements, and contained notably body No. 2 furnished with mobile filaments, it was found that very dilute solutions of quinine—a drop of a solution of a salt of quinine containing 1 : 1,000—quickly arrested the motion of the mobile filaments, and caused the parasite to assume its "cadaveric form."

The writer has elsewhere shown[1] that laboratory experiments made to determine the germicidal power of quinine do not justify the belief that this agent can be introduced into the circulation in sufficient quantity to arrest the development of such an organism as the *bacillus malariæ* of Klebs and Tommasi-Crudeli. "A dose of ten grains of quinine, if absorbed at once and retained in the blood, would not constitute, in an adult weighing one hundred and sixty pounds, $\frac{1}{150}$ part of one per cent. (1 : 15,000) of the entire mass of blood." But the experiments of Professor Ceri[2] and others,[3] show that this amount would be entirely inadequate to prevent the development of bacteria in culture fluids, from 1 : 800 to 1 : 3,000 of a soluble salt of quinine—muriate—being required.

As long ago as 1871, Vulpian,[4] from experimental data, arrived at the conclusion that it would be necessary to administer more than thirty grammes of muriate of quinine to patients with malarial fever, in order to destroy vibrioniens in their blood. We have also very satisfactory clinical evidence in support of the conclusion, based upon biological experiments, that it is impracticable to destroy bacteria in the blood of a patient by the administration of the salts of quinine, or by any other known germicidal agent. The experience of Carter,[5] Pepper,[6] and others, shows that quinine in full doses has no power to arrest a paroxysm of relapsing fever, or to prevent a relapse. Carter says: "In practice, however, the blood-spirillum and the febrile symptoms remain unaffected after quinine given largely, to cinchonism, after narcotism by chloral and the freest exhibition of spirituous liquors; also, after the administration of the carbolates and very large doses of the salicylates. Hence, as yet, there is no evidence that the drugs named, when administered variously and in doses consistent with safety, possess a manifest parasiticidal efficacy in relapsing fever. . . . Interesting details have been published, and some were acquired in India, showing that large doses of quinine and of sodium salicylate, given persistently at short intervals through the entire first apyretic period of relapsing fever, have entirely failed to prevent or even mitigate the first relapse."[7]

It is evident, then, that the results of laboratory experiments are in accord with clinical experience as regards organisms of this class—*bacteria*. But, on the other hand, there is evidence that the *infusoria* are far more susceptible to the action of quinine, and the data available rather favor, than contradict, the assumption that the specific curative power of this drug may depend upon its restraining influence upon the development of an *amœboid* blood-parasite like that discovered by Laveran. And in support of this hypothesis we have the tes-

timony of Laveran, and of the Italian observers mentioned, as to the disappearance of the parasite, *pari passu*, with the morbid phenomena, under the influence of the administration of quinine, and the direct experiments of the first-named author, showing that this drug in very dilute solution promptly arrests the vital activity of the parasite discovered by him.

Further researches are no doubt necessary to establish definitely the claim of this amœboid parasite to be admitted into the family of recognized "disease germs," and it may be that we shall find eventually that its life-history is more complex than is indicated by the observations of Laveran, or that he has not properly interpreted what he has seen. But I cannot doubt the fact that the objects described by him as found in the blood of malarial-fever patients are in truth parasitic micro-organisms; and the evidence above recorded seems to me to support very strongly the inference that this peculiar blood-parasite is directly concerned in the etiology of the malarial fevers.

If this proves in the end to be true, it will be another illustration of the fact that we often arrive at the truth through a series of errors, and that veritable discoveries are often viewed with unreasonable scepticism because they do not correspond with preconceived ideas; while pseudo-discoveries which fall in with the current of prevailing opinion may receive general credence upon a very poor foundation of experimental evidence.

Post Scriptum.—Since writing the above, I have had an opportunity to verify the presence of the amœboid organism, demonstrated to me by Drs. Marchiafava and Celli at the Santo Spirito Hospital in Rome, in the blood of a malarial patient in this country. Through the courtesy of Dr. R. Nordman, resident physician at the Bay View Hospital, I received, on the 24th inst., a specimen of blood drawn from the finger of a patient at the outset of an intermittent paroxysm. The blood had been collected and mounted by Dr. Nordman, in accordance with my directions, and was brought under the microscope as quickly as possible. I was fortunate enough to find the amœboid organism, which I had previously seen in Rome, and was able to demonstrate its presence in the interior of a red blood-corpuscle, and its vital movements, to Professor Wm. H. Welch, in whose laboratory the microscopical examination was made, and to several other medical gentlemen who happened to be present.

GEO. M. STERNBERG.

BALTIMORE, March 26, 1886.

PUNISHED FOR NOT ATTENDING A PATIENT WHEN SUMMONED.—A correspondent of *The Lancet* calls attention to the punishment of a Russian physician who is being sued for refusing to treat a patient. Until the termination of the process he is prevented from leaving his dwelling-house; and as the lawsuit has lasted fifteen months (and, it appears, is not likely to be speedily concluded), all professional occupation, excepting in the cases of patients who are well enough to visit him, is impossible. He has also been prevented from going to a watering-place, to which he has of late years been in the habit of repairing for his health's sake, and this prohibition will endure until the suit is ended. Refusal to attend a patient in Russia evidently means ruin to the luckless practitioner.

TO PREVENT COAGULATION OF THE BLOOD.—A student in Professor Stricker's laboratory, Herr Ernest Freund, has suggested a most simple and convenient method of preserving blood in the fluid state. His plan consists in coating the interior of a glass vessel with pure oil. Into this receptacle blood freshly drawn is poured, and a layer of oil is then run over the surface exposed to the air. In this way, it is stated, fresh blood may be kept from coagulating for days if necessary. If this assertion be true, the discovery may be turned to great advantage in the process of transfusion of blood.

A CASE OF TRAUMATIC TETANUS, FOLLOWED, EIGHT MONTHS LATER, BY TETANOID SYMPTOMS AFTER VACCINATION.

WHISKEY TREATMENT IN EACH INSTANCE, WITH RECOVERY.

BY HOBART CHEESMAN, M.D.,

NEW YORK.

EDWARD T——, American, aged five, bright, well developed, and previously healthy, but of rather nervous temperament. I first saw the patient, a dispensary case, in May, 1882. Twelve days previously he had wounded the sole of his foot by stepping upon a fragment of glass, and two days previously symptoms of tetanus had begun to develop. There was no sign of inflammation in the wound, and it seemed insignificant, but had not healed. He had well-marked and characteristic symptoms of tetanus. A dose of calomel was given, and a teaspoonful of whiskey and half a cup of milk ordered every hour. The whiskey was increased at each succeeding visit, it doing good and producing no symptoms of intoxication. On the third day I directed the mother to give a tablespoonful every hour, and if this failed to quiet him after a number of doses, to give more. She declared that a tablespoonful was given every hour until two o'clock the next morning, but without intoxicating or putting him to sleep. In desperation she then gave a tumbler half full. This produced the desired effect, and he slept for several hours, awaking much better, and having no more severe paroxysms. From this time he rapidly improved, and was well in about two weeks, and remained so until February, 1883. After taking the half-tumbler dose of whiskey he could not tolerate it, but would show symptoms of intoxication if a teaspoonful were forced upon him. During this attack there were no head symptoms.

On February 22, 1883, I was summoned to him again. He had been vaccinated by the Health Board on February 1st. In place of the vaccination I found an ulcer half an inch in diameter, skin deep, and with clear cut edges and inert surface. He had complained occasionally for a week of pains in it, and in the front of the wrist and forearm, and lately had had cramps in this hand, and could not hold his food in it. Some feverishness had been noticed, and also nocturnal incontinence, and a desire, when at play, to pass urine on any little disturbance. The appetite and bowels had been normal. On the morning of the 21st he had complained of headache, and in the evening vomited, became delirious, and stiff in the neck and back; had spasms, with grimacing, setting of the jaws, and pain in the stomach. He had slept none since the night of the 20th. The mother thought he had diphtheria, because of difficulty in swallowing and swelling at the sides of the neck, but my examination of the throat discovered a little frothy saliva and mucus only. I found the axillary temperature 102.3° F., the pulse rapid, especially during paroxysms, lively delirium, extreme restlessness, some stiffness of the jaw, bulging of the muscles at the side of the neck, stiffness of the back, with a tendency to opisthotonus, and signs of epigastric pain. At intervals of ten or fifteen minutes there were paroxysms, in which the jaws were firmly set, with the lower one protruding, grimacing, extreme opisthotonus, in which the lower extremities participated, being rigidly drawn back or violently thrown about, the patient sprawling over the bed and screaming with pain and delirium. The upper extremities were not noticeably affected, and there was no frothing at the mouth, no biting the tongue, but there was severe dyspnœa. On attemping to administer fluid the mouth had to be forced open with the spoon, and the patient would not swallow until he was forced to by holding his nose. Articulation was defective, but the voice strong. The sounds of the heart and lungs were normal, the pupils equal, dilated moderately, and active, the eyes rather prominent and staring, tongue coated.

Treatment.—I gave calomel, grs. iij., ordered a cup half full of milk and a teaspoonful of whiskey every hour, and quinine, gr. jss., every four hours. At noon the next day I found him with the same symptoms aggravated, and ordered, in addition, a mixture of chloral, bromide, and paregoric. I was sent for again at nine P.M., and found, in addition to the other symptoms, which were constantly getting worse, violent palpitation of the heart; the whole chest-wall could be seen to vibrate with its violent and tumultuous beating. This so aggravated the dyspnœa that the mother had feared that he would suffocate during the paroxysms. Temperature was 102.8° F. At 9.30 I gave him two large tablespoonfuls of undiluted whiskey directly after a fit. This excited another mild fit, but he soon after got quieter, the pulse declining to 100 and the palpitation nearly ceasing, and at 9.50 he fell asleep. In five minutes he awoke with a fit. As soon as possible I gave another tablespoonful of whiskey, and he was asleep again at 10.10. The spasms had lately affected the upper extremities, which during the paroxysms were extended and held out rigid and trembling.

At 10.20 continues restless. After a tablespoonful of whiskey he sleeps restlessly, and wakes at 10.30 with a fit, which is milder than usual. Two tablespoonfuls of whiskey are given after the fit. The face continues rather pale, the eyes are more natural, the pupils smaller, and he speaks rationally once, for the first time. Red patches appear on the face; they soon spread, and the face becomes flushed. At 11.55 he wakes with a fit. After it subsides he is given two tablespoonfuls of whiskey, and sleeps until five minutes after twelve, awaking without a fit for the first time; he passes four ounces of normal-colored urine. At 1.5 o'clock A.M., after sleeping quietly for another hour, he wakes without a fit, takes a cup of milk and two tablespoonfuls of whiskey, and then goes to sleep directly. I left him at 1.30 still sleeping. From 9.30 P.M. to 1 A.M. he had taken ten tablespoonfuls of whiskey, and still did not seem to be drunk. The whiskey was of good age and full strength. During the next thirty-six hours about a pint and a half of whiskey was required to control the violence of the symptoms; in the twenty-four following this period about three or four ounces, after which an occasional dose, and that only as a stimulant, he having, after the fits of convulsions ceased, occasionally, for several days, attacks showing symptoms of collapse, with palpitation and præcordial pain. Whiskey always relieved them.

On the 24th, about noon, I visited him, and he answered rationally, but continued for two days after this more or less delirious. At this visit he was covered with a rash, scarlatina-like, but it soon faded and had disappeared at next visit.

On the 25th I noticed, for the first time, that the left hand was held constantly in a cramped condition, with the thumb and little finger crossed. He complained that needles were sticking through his temples, and of pain in the top of his head. Two leeches were applied in front of each ear, but he continued to complain of the same pains for several days. He had at this visit very decided Cheyne-Stokes respiration. This was noticed on one or two other occasions, in a less degree.

On the 26th, loud, coarse mucous râles were heard all over both lungs, and he raised a frothy sputum like that in the fauces. These symptoms lasted two days.

On the 27th he kept saying that there were worms in his feet, and that the soles were sore, and his mother declared that in the evening both feet and legs became hot and considerably swollen, and remained for three or four hours in this condition.

On the 28th the tongue began to clear, and on March 2d the temperature was normal, and remained so thereafter. It had ranged as follows: 22d, 102.5°; 23d, 102.3°; 24th, 102.5°; 25th, 102.8°; 26th, 101.8°; 27th, 101.3°; 28th, 101°, taken each day in the afternoon. On March 6th considerable stiffness and soreness remained in the neck and back, but it was diminishing rapidly, and had disappeared from other parts. Formerly, when raised to a sitting posture, the spine would curve in and be held very rigid, while he would cry with the pain.

On March 12th he seemed well, but was rather nervous, and the eyes had a wild, startled expression; the same symptoms had been noticed after the former attack. During convalescence, his mother says, he would lay all day flat on his back, very listless, appearing too exhausted to care for anything. A year later he remained well, but had not been so bright as formerly, and showed more nervousness.

This case presents all the characteristic symptoms of tetanus, viz., presence of an unhealed wound; cramps beginning in the wounded limb (this is a symptom sometimes but not often observed); stiffness of the jaw, swelling at the sides of the neck and dysphagia were early symptoms, followed by stiff back and lower extremities, and opisthotonus; at intervals there were violent and painful spasms of these parts and grimacing, while the upper extremities were not noticeably convulsed until the disease had progressed to its most violent stage; epigastric pain, indicative of cramp in the diaphragm; severe dyspnœa; indistinct speech; slight disturbance excited a fit; pupils dilated (the usual condition), but otherwise normal; no loss of control over the bladder or bowels, nor priapism; sleeplessness; no tongue nor cheek biting; accumulations of a frothy character in the fauces; muscular stiffness and soreness remaining for many days (most easily explained on the theory of the tetanus I think). Superadded to these are other symptoms not usually associated with the disease. Whether they signify anything more than sympathetic and functional disturbance I leave the reader to decide. The delirium was early and conspicuous for several days. It is well known that head symptoms may develop during tetanus, especially in children, and sometimes in adults during the latter stage of the disease. There were other nervous phenomena, which, I presume, are of about the same import as the delirium. Is it surprising that extraordinary symptoms of this nature should occur during this disease in a nervous child, when we consider the mobility of the nervous system and the close sympathy between its different functions? As to the range of temperature, I do not know that it is more satisfactorily explained by meningitis than by tetanus.

I have not seen it stated that the heart is ever affected by cramp of its muscles in tetanus, but does not the character of the palpitation noticed on the night of February 23d suggest this as a plausible explanation?

It might be interesting to inquire if the former attack was the predisposing cause of the second, and, if so, how long after an attack of tetanus would it be safe to vaccinate the patient. For evident reasons such an emergency will not often arise.

The effect of the whiskey was so decided and beneficial that I think it should be tried in similar cases oftener. That large quantities are tolerated in tetanus is well known, but not so often remembered, perhaps, as it deserves. Why should not this peculiarity furnish an urgent indication for its use in tetanus, as it is thought to do in snake-bite? I believe its success in tetanus, as in snake-bite, will be found to depend upon its being given in the largest quantities that the patient will bear.

244 West Fifty-sixth Street.

RACHITIS, OR RHACHITIS?—A somewhat animated discussion is in progress between Virchow and certain other German physicians as to the correct spelling of the scientific term for rickets. Etymologically rhachitis is certainly correct, but custom, which often knows not etymology, would seem to have established rachitis upon too firm a basis to be overthrown.

FLUID EXTRACT OF KAVA KAVA IN THE TREATMENT OF GONORRHŒA.

By HERBERT C. ROGERS, M.D.,

ADJUNCT SURGEON, LONG ISLAND COLLEGE HOSPITAL, BROOKLYN.

For several years I have substituted for the balsam copaiva, or cubebs, or both, according to circumstances, the fluid extract of kava kava. I have rarely found copaiva or cubebs alone sufficient for the cure of the disease. The former very often causes annoying skin-eruptions before it has produced the effects for which it has been prescribed, and I have been obliged to lay it aside. Cubebs has not proved more successful in my hands. I have tried cubebs alone, in powder and in a fluid extract, and when it has not succeeded I have combined it with the balsam copaiva. One of the great objections to the use of copaiva is its extremely nauseating taste, and another is the amount of disturbance it produces in the stomach. The fact last stated is the reason why I have given up entirely the use of copaiva in my hospital practice. The cases one meets with in a large hospital practice, suffering from gonorrhœa, are generally those of broken-down subjects who have more or less catarrh of the stomach, and in which their digestion is very poor.

A patient and friend, when abroad a few years ago, unfortunately contracted a gonorrhœa while visiting Paris. He wrote to me and asked for a prescription. I sent him one containing balsam copaiva and fluid extract of cubebs. Several months later the patient called on me at my office, told me he had received my prescription, and had it prepared, but that after taking a few doses he was compelled to give it up, as it caused so much disturbance to his stomach. He went a few days without treatment, when his testicle commenced swelling and caused him so much annoyance and pain that he was compelled to send for a surgeon, who strapped the organ, and ordered him some medicine to take, remarking at the same time that it was the new drug for gonorrhœa. In two weeks my friend was all right.

It so happened that another one of the party contracted the same disease shortly after, and was also cured with but little loss of time. This gentleman was so much pleased with the medicine (having had the disease several times, and always having copaiva or cubebs prescribed for him, which invariably produced more or less nausea and destroyed his appetite) that he secured a copy of the prescription for future use.

After my friend had related the above, I asked him if he would try and obtain for me a copy. This he did in a few days. The prescription was for infusion of kava kava, half-ounce four times a day.

Having a little leisure, I looked the matter up, and found that the drug has been used in France for a considerable period. It was first recommended for gonorrhœa about 1857.

The best account of the drug that I have been able to find is in the *New Remedies* for October, 1876. From this I give a short extract:

"Kava kava is a shrub about six or eight feet high, with stems varying from one to two inches in thickness. The leaves vary from six to eight inches in length, and are nearly as broad as they are long. They are cordate, tapering somewhat suddenly into a very short acute apex. The petiole is usually one to two inches long, and is dilated at its base. The root is large and fibrous, but rather light and spongy in texture. The root has a pleasant odor, resembling lilac. It has a slightly pungent taste, and causes an increased flow of saliva, with a slightly astringent sensation in the mouth, with a little bitterness. The root and base of the stems are the portion generally used.

"The form in which it is generally used in medicine is an infusion made by macerating about one drachm of the scraped root in a quart of water, and also a fluid extract, one minim representing one grain of the root. The latter preparation is the best suited for general use.

"The action of kava-root appears to vary with the amount taken. In small doses it is said to act generally as a stimulant and tonic; but when taken in large doses it produces intoxication, which differs from that caused by alcohol in being of a silent and drowsy nature, accompanied by incoherent dreams, the drinker not being quarrelsome or excited. The taste of the plant is pleasant, while its bitterness improves the appetite and does not produce nausea."

During the past two years I have treated in all 105 cases of gonorrhœa; of these, 34 were in private practice, and 71 were at the hospital. The majority of those treated in hospital practice had had the disease once or oftener previous to the attack from which they were suffering when they first consulted me. One patient, a Swedish sailor, claimed that he had had the disease a dozen times, and stated that he had been operated upon by the late Dr. George Atkinson for stricture. When I first saw him he was suffering from a sharp attack of gonorrhœa; his testicle was swollen, and altogether he was in a bad condition. He was ordered to take fluid extract of kava kava in thirty-minim doses four times a day, and to apply a wash of liq. plumbi et Aopii to the inflamed organ. In three weeks the discharge had dwindled down to a watery condition, which remained in spite of all I could do. After trying all known means, I was compelled to cut him. He stood the operation badly, and made a slow recovery; but in two months the wound had healed, and the discharge had entirely dried up. This case was the longest one on my table.

Of the 71 cases treated at the hospital, 43 were discharged, in from six to nine weeks, cured; 13 improved, but were lost sight of before two weeks had passed; 7 never returned; and in 8 the drug did not seem to have any effect.

Of the cases in private practice, nearly two-thirds were suffering from the disease for the first time when they consulted me. The longest period that a patient of this class remained under my care was thirteen weeks. This case was that of a gentleman, and a member of one of the New York clubs. He was a bachelor, addicted to good living, and particularly fond of champagne. In spite of my warnings, after he came under my treatment, he took his wine occasionally, with the invariable result of starting up a brisk discharge. After repeating this several times, he at last left his wine alone for three weeks, when the discharge entirely ceased.

The shortest period that any patient suffering from this disease has been under my care was twenty-seven days. This was the case of a young man at college, who, while spending a few days at home, chanced to contract a mild gonorrhœa. When he first consulted me about the discharge, he could hardly believe what I told him. To convince him, I examined the young woman with whom he had had intercourse, and found her recovering from gonorrhœa. She had been treated by a New York surgeon, who informed me by letter that she had been under treatment for six weeks. It so happened that this young woman shared her favors with several young men. The morning following this examination, I was called upon by a friend of the last patient, who acknowledged having had intercourse with this same girl on the morning of the day she called upon me. Having learned that his college friend had contracted his disease from her, he was greatly alarmed, fearing that he also might have taken it. I examined him carefully, but could not discover the least evidence of any trouble. To pacify him, I injected his urethra with a solution of hyd. bichlor., one in five hundred, and placed him on twenty-minim doses of kava kava three times daily. At the end of one week he presented no evidence of disease, and was discharged.

The average period of gonorrhœa patients under my

treatment has been about nine weeks. I had but few complications. In only three cases was there swelling of the testicle. About one-fifth suffered from chordee.

In none of the cases was there any trouble with the stomach resulting from the use of kava kava. In over one-half the appetite was improved and increased. In one case the peculiar effect of the drug was manifested. The patient was a married man, whose wife was in the country when he contracted the disease. As he expected her home in three or four weeks, he was anxious to get well. Under the influence of this feeling, he took much more of the drug than had been prescribed. Instead of taking it every four hours, he took it every three. At the end of the third day, I was sent for. I found my patient suffering from a mild form of delusion. I stopped the medicine and gave a small dose of opium. By morning he was feeling all right. This is the only case that showed this symptom.

My usual prescription is from twenty to thirty minims of the fluid extract of kava kava, in water, to be repeated every four or five hours, as the case may be. The patient is restricted to plain food and plenty of milk, with Vichy water. He is not allowed to indulge in alcoholic drinks, in tea or coffee. Smoking (if he has the habit) must be given up for the time. The bowels must be moved gently, and care must be taken that the patient does not become constipated. From what I have seen, however, in connection with the use of the drug, I am inclined to think that it is mildly laxative, as all my patients, while taking it, had one or more movements from the bowels each day.

News of the Week.

The Act for the better Preservation of the Health of Children in institutions has been passed by the Assembly, and now goes to the Governor to receive his signature before becoming a law. This act has been indorsed by the medical societies of both county and State, and its passage has been urged by the Board of Health. The Record has repeatedly urged the great need of this legislation. No more important measure of sanitary reform than this has ever received the attention of our State Legislature.

The Report of the National Board of Health for 1885 has just been issued from the Government press at Washington. It is a volume of three hundred and sixty-three pages, and contains a full history of epidemic diseases during the year in different countries, especially of cholera and small-pox, and the preventive measures that have been adopted in different localities, besides other matters of interest to the profession. Physicians can now secure copies through their representatives in Congress, by writing them personally.

The President and Anatomical Study.—The daily papers report from Washington that the Senate took up last week the President's veto of the bill "To Provide for the Promotion of Anatomical Science and to Prevent the Desecration of Graves." The bill relates to the District of Columbia, and provides that the unclaimed bodies of deceased paupers, now required by law to be buried at the public expense, might be turned over to the medical colleges of the District of Columbia. The President declined to approve the bill, on the ground that certain of its provisions were indefinite and did not supply sufficient safeguards. After a short debate the Senate refused to pass the bill over the President's veto—yeas 6, nays 48.

The Medical Record:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published by

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 8, 1886.

AMERICAN MEDICAL ASSOCIATION.

We learn from our St. Louis despatches that the American Medical Association voted to leave the present Executive Committee of the International Congress undisturbed in its work. This Committee has elected Dr. N. S. Davis President of the Congress, and Dr. J. B. Hamilton Secretary-General.

There was no opposition made to these changes or to the adoption of the present policy. The much dreaded descent of Philadelphia's delegates upon the Association did not occur. All was harmony and smiles.

The attendance at the meeting was fairly good, but naturally was made up almost entirely of men from the West and Southwest. That part of our great country is determined to hold an international congress which shall be truly representative.

A MONUMENT TO THE LATE DR. AUSTIN FLINT.

We believe it wise and just to create memorials of those great physicians whose work has left an impress upon our history. A monument is to be erected to the memory of Dr. Marion Sims and of Dr. Rush. What more appropriate than that the name of Austin Flint, Sr., receive the same recognition from the profession. A movement to secure a fund for the erection of a suitable monument would meet a hearty support from all American physicians.

LAPAROTOMY IN ABDOMINAL WOUNDS.

We do not know whether or not *The Lancet* is trying to poke fun at some of our eminent professors. If not, it shows that it possesses a remarkably chaotic notion of American surgical work. In a recent elaborate leader upon the "treatment of perforating wounds of the abdomen," it says that "the most important result" of the labors "of American surgeons in this line, since the death of Garfield, is a paper lately read by Professor F. S. Dennis, of this city, on the subject." It is rather too bad to load down Dr. Dennis with such a compliment. It is very well known to American surgeons that it was the cases of Dr. William T. Bull, and subsequently those of Dr. J. B. Hamilton, and others, which especially turned the attention in this country to laparotomy in abdominal wounds. This Dr. Dennis himself acknowledges, in his very thorough and creditable article.

Reports of Societies.

American Medical Association.

Thirty-seventh Annual Meeting, held in St. Louis, Mo., May 4, 5, 6, and 7, 1886.

(By Telegraph to The Medical Record.)

TUESDAY, MAY 4TH—FIRST DAY.

THE Association met at the Exposition Building, and was called to order at 11 A.M., by Dr. Le Grand Atwood, of St. Louis, Chairman of the Committee of Arrangements.

DR. ATWOOD introduced Dr. Brodie, President. Prayer was offered by REV. MONTGOMERY SCHUYLER, D.D.

THE ADDRESS OF WELCOME

was given by HON. D. R. FRANCIS, Mayor of St. Louis.

DR. ATWOOD welcomed the Association on behalf of the medical profession of St. Louis. The ex-Presidents were invited to take seats upon the platform, and Drs. N. S. Davis, of Chicago; J. M. Toner, of Washington; T. G. Richardson, of New Orleans, and D. Yandell, of Louisville, were present.

Dr. Atwood then announced the programme for the entire meeting, with entertainments numerous and inviting. He also announced the presentation of

PROTESTS AGAINST DELEGATES

from the following organizations: Philadelphia County Medical Society; Davidson County, Tenn.; the Tri-State Medical Society, the Mississippi Valley Medical Association, the Tennessee State Medical Society. All these were referred to the Judicial Council.

The following gentlemen were elected

MEMBERS BY INVITATION:

Colonel Manfred Johnson, of McHenry, Ill.; Drs. William W. Morrison, of St. Louis; H. J. McKellops, of St. Louis, W. H. Atkinson, of New York.

DR. WILLIAM BRODIE, of Detroit, Mich., then delivered

THE PRESIDENT'S ADDRESS,

in which, after referring to the facts that no epidemic disease had invaded the country during the last year, that a general state of health had been given to the members, then made special reference to the inroads made among our ranks by the removal by death of Drs. Bowling, John L. Atlee, and Austin Flint, of whom he gave brief biographical sketches. From this he passed to a sketch of the history of the organization of the Association, beginning with 1846, when it was conceived by Dr. Hayes, of Philadelphia; special reference was made to the influence of the Association on the question of the elevation of the standard of medical education. The influence of the Code, as sustained by the Association, was dwelt upon, and the chief interest in this part of the address centred in the statement that the movement in the State of New York against it was due chiefly to financial considerations.

Dr. Brodie then referred by title to the papers which had been read before the Association, and which had made a healthy impression upon the mind of the profession.

He regarded the Association as no pent-up Utica, but as sufficiently broad to meet all the necessities of the profession, through its Sections, and, therefore, that additional national associations were unnecessary. He favored the adoption of resolutions sustaining the National Board of Health.

He recommended the abolition of the metric system from the "Transactions" of the Association. He recommended the formation of a Section on Dermatology and Syphilis, also that the secretaries of Sections be permanent officers, subject to removal in the wisdom of the Section. He spoke of the success of the *Journal*, and directed attention to the by-laws, which make every paper received by the Association its exclusive property, and said that it was improper to give copies to outsiders; but that if medical journals were sufficiently enterprising to employ competent men to take notes from which abstracts were to be made, while the papers were being read, no obstacle should be thrown in the way. Practically, there was no difference between a patented and a proprietary medicine, and whoever lent his name to the support of either should be disciplined in local societies.

With regard to the question of establishing branches, after the manner of the British Medical Association, he recommended that the subject be referred to a committee for report.

CONCERNING THE INTERNATIONAL MEDICAL CONGRESS,

all that remained to be done was for the Association to adopt the report of the Committee, which would soon be made, and thus relieve itself of all further responsibility in the matter.

He entered into a history of the Congress, and closed with an expression of the belief that the general sentiment of the profession was in favor of adopting the report of the Committee, and when adopted that personal feeling should yield to the common good of the profession.

The address was closed by the President returning to the Association his thanks for the honor it had conferred upon him.

DR. MURPHY, of St. Paul, moved that the thanks of the Association be tendered to Dr. Brodie for his address; that it be referred to the Committee on Publication, and that all its recommendations and special points be referred to the appropriate committees. Carried.

A memorial from the Woman's Christian Temperance Union was introduced, and referred to the Committee on State Medicine.

DR. J. S. LYNCH, of Baltimore, from the Committee on

PRELIMINARY ORGANIZATION OF THE NINTH INTERNATIONAL MEDICAL CONGRESS,

reported that the Committee had adopted rules for the organization, had nominated the general officers for the Congress, Local Committee of Arrangements, etc., and respectfully submitted the list.

DR. GIHON, of Washington, moved that the report be accepted and adopted. Unanimously carried.

DR. HENRY SMITH, of Philadelphia, moved a reconsideration of the vote just taken.

DR. GIHON moved that the reconsideration be laid upon the table. Carried.

DR. N. S. DAVIS introduced the following

AMENDMENT TO THE BY-LAWS:

Section two, paragraph three, shall be amended so as to read: "On the second day of each annual meeting, each Section shall nominate its own officers to serve for the next ensuing year; their duties to commence with the close of the annual meeting at which they are nominated, and to continue until their successors are elected." The proposed amendment gave rise to discussion, which was participated in by Drs. Roberts, of Tennessee; Quimby, of New Jersey; Kinloch, of South Carolina; E. Smith, of Michigan; Reynolds, of Kentucky; Murphy, of Wisconsin; Murdock, of Pennsylvania, who spoke against it, and by Dr. Allport of Illinois, who favored the amendment. A rising vote was taken, and the President declared the amendment adopted by a four-fifths vote.

DR. A. REEVES JACKSON, of Chicago, presented a paper on the "Use of the Intra-uterine Stem in Flexion," which was referred to the Section on Diseases of Women.

Dr. William W. Morrison, of St. Louis, presented a paper, which was referred to the Section on Dental and Oral Surgery.

The Association then adjourned, to meet at 10 A.M., May 5th.

Wednesday, May 5th—Second Day.

The Association was called to order by the President, after which prayer was offered by the Rev. M. Rhodes, D.D.

Dr. J. A. Thacher, of Cincinnati, was elected a member by invitation.

The Secretary announced as

THE COMMITTEE ON PRESIDENT'S ADDRESS,

Drs. Murphy, of Wisconsin, Gihon, of the Navy, and Garcelon, of Maine.

The Secretary announced the following

COMMITTEE ON NOMINATIONS.

District of Columbia, J. W. Bulkley; Arkansas, P. O. Hooper; Colorado, J. W. Graham; Connecticut, W. C. Wile; Dakota, J. B. Van Velsor; Florida, T. O. Summers; Georgia, J. W. Bailey; Illinois, John E. Owens; Indiana, Thomas B. Harvey; Iowa, W. Watson; Kansas, C. V. Mottram; Kentucky, W. H. Wathener; Louisiana, Joseph Jones; Maine, Charles E. Webster; Maryland, G. H. Rohe; Massachusetts, E. W. Cushing; Michigan, H. O. Walker; Minnesota, H. H. Kimball; Mississippi, P. W. Rowland; Missouri, G. F. Dudley; New Mexico, W. R. Tipton; Nebraska, W. M. Knapp; New Jersey, E. L. B. Godfrey; New York, E. S. F. Arnold; North Carolina, C. J. Ohagan; Ohio, H. J. Sharp; Pennsylvania, J. C. Lang; Rhode Island, H. R. Storer; South Carolina, R. A. Kinloch; Tennessee, Duncan Eve; Texas, J. F. Y. Payne; Vermont, A. T. Woodward; Virginia, G. B. McCorkle; West Virginia, G. W. Baird; Wisconsin, W. T. Galloway; United States Navy, W. T. Howard; United States Marine Hospital Service, W. Wyman.

Dr. Savage protested against Dr. Eve of Tennessee until the protest against the Tennessee State Medical Society should be reported upon by the Judicial Council.

Dr. Nicholas Senn, of Milwaukee, then delivered

THE ADDRESS OF THE CHAIRMAN OF THE SECTION ON SURGERY AND ANATOMY

in which he directed special attention to

THE PRESENT STATE OF ABDOMINAL SURGERY

by a condensed account of the advancement which had been made within the last few years in that department. He limited his remarks to the consideration of such injuries and lesions of the abdominal organs as were liable to be presented to physicians and general surgeons, aiming particularly to point out

THE LIMITATIONS OF ABDOMINAL OPERATIONS,

and to draw a distinct line between feasibility and justifiability. The first topic was penetrating wounds of the abdomen. The Chairman mentioned the distinctions between punctured and gunshot wounds, and spoke of these as important with reference to diagnosis and treatment.

EXPLORATIVE LAPAROTOMY

had for its objects positive diagnosis, arrest of hemorrhage, restoration of breach of continuity, and removal of extravasations. Dr. Senn prefers the bichloride to carbolic acid, and for uniting divided ends of intestine the Czerny-Lembert suture was the only one which should be used. If any doubt exists concerning the aseptic condition of the peritoneal cavity, a drainage-tube should be inserted. He insisted upon the justifiableness of explorative laparotomy in all doubtful cases.

LAPARO-COLOTOMY

was the next topic, which was followed by that of subcutaneous laceration of intestines. Then came intestinal obstruction. The treatment of this condition by laparotomy was in its infancy, yet sufficient good results had been obtained to stimulate additional efforts in studying its limit of application. The results would improve as soon as physicians recognized the insufficiency of the expectant plan of treatment. Intussusception and enterostenosis followed, and for internal strangulation the rules given by J. Greig Smith were endorsed. These were followed by enterectomy, rupture of the diaphragm, and

TREATMENT OF PERITONITIS BY ABDOMINAL SECTION AND DRAINAGE.

The last had been most successful in cases where the disease had not become diffused, and where the original cause could be removed. Tubercular peritonitis was considered next, and this was followed by gastrotomy, which was of questionable propriety in cases of malignant disease, but was recommended in all cases of non-malignant stricture. Pylorectomy, duodenostomy, and jejunostomy were the last topics considered.

The general conclusion was that abdominal surgery was a legacy of inestimable value, left to us by McDowell, Gross, and Sims, that it should be cherished and studied, and that our knowledge of it should be carefully cultivated.

Dr. H. F. Campbell, of Georgia, ex-President, was invited to take a seat upon the platform.

Dr. S. C. Gordon, of Portland, Me., then delivered

THE ADDRESS OF THE CHAIRMAN OF THE SECTION ON OBSTETRICS AND DISEASES OF WOMEN,

in which he said that nothing remarkable had been done or discovered in these departments during the last year. He could only emphasize matters which had been alluded to, and perhaps weigh inferences which had been made on topics that had been more or less discussed. With reference to attending cases of labor after having made an autopsy or while in attendance upon cases of puerperal fever, etc., he believed that the weight of opinion sustained the view that with proper regimen and absolute cleanliness the daily work of the physician could be safely continued without delay or anxiety. The criminality was in the neglect to take proper precautions, and time might not be an element of safety if these were not observed. Concerning the early signs of pregnancy, he regarded Hegar's test as specially valuable, and one which was applicable early, namely, increase in the anterior curvature of the uterus, with increased elasticity of the uterine wall. For the obstinate vomiting of pregnancy no one measure was of so much value as forcible dilatation of the cervical canal below the internal os. In producing premature labor he recommended the use of the bougie, and when done on account of disproportionate head the eighth month was the most favorable time. He favored the use of a nutritious diet during the parturient period. For ameliorating suffering and shortening the process of labor anæsthetics and the forceps had done much, and had thus prevented many of the injuries formerly incident to the parturient process. Under the judicious use of the forceps vesico-vaginal fistula was diminishing in frequency.

The treatment of the placenta in both normal labor and abortion had been written of so satisfactorily by Pajot that nothing need be added. At full term the placenta was best removed by prompt and gentle traction on the cord, and the earlier after the delivery of the child this was effected the more easily could it be done and the less evils come therefrom. Forcible removal of membranes in abortion was by no means the safer prac-

tice. Remove them if it can be done without much trouble or instrumental interference, otherwise carefully tampon the vagina, and less harm would be done than by resorting to forcible means.

In the department of gynecology only one theme was introduced, and that was the removal of uterine appendages, included under the three operations known as Battey's, Tait's, and Hegar's. After making some remarks, the chairman spoke particularly of hysteria and its relation to diseases of the uterine appendages. This part of this subject was discussed at much length, and accompanied by the histories of illustrative cases in which cure had been effected by the operation. He had removed the uterine appendages in twenty-five cases, and with only one death. The conclusions reached by the speaker were based upon his study of the subject and the favorable results obtained in these cases.

Dr. A. L. Gihon, of Washington, chairman of the

RUSH MEMORIAL COMMITTEE,

reported that in obedience to the resolutions adopted by the Association at its last annual meeting, the committee had been instituted by the appointment of one member from each of the States, Territories, and national services represented in the Association, and that the Standing Committee thus organized would proceed at once to collect funds for the erection of a statue of Dr. Benjamin Rush, in the city of Washington, by the members of the profession of medicine in the United States. No further time should be lost by the medical profession in completing its enduring testimonial of one who was not only a great physician and teacher of medicine, philosopher, philanthropist, and accomplished writer, but a fearless patriot and founder of the Republic, a signer of the Declaration of Independence, an officer of the army of the Revolution, and one of the authors of the Federal Constitution.

With this announcement the Rush Memorial Committee will at once undertake the work of obtaining subscriptions, which have been limited by resolution of the Association to one dollar from each member of the profession of medicine in the United States, and receiving such voluntary donations as may be made by persons interested in this great undertaking. The secretary of the committee is George H. Rohe, of Baltimore, and the treasurer, J. M. Toner, of Washington, D. C.

The report was accepted and referred to the Committee on Publication.

Dr. I. N. Quimby, of New Jersey, moved to take from the table the resolution introduced at the last annual meeting, providing for a new section, namely, one on medical jurisprudence, which was carried.

A motion for its adoption gave rise to discussion by Dr. Logan, of New Orleans, who thought that the necessity for such a section did not exist, and by Dr. Campbell, of Georgia, who originated the idea of establishing this section.

The resolution was adopted.

The President acknowledged the receipt of a communication from the Texas State Medical Society, extending its congratulations to the Association on its growth and usefulness, which was accepted and ordered entered upon the minutes.

The Association then adjourned to meet on Thursday morning, at ten o'clock.

Thursday, May 6th—Third Day.

The Association was called to order by the President.

Prayer was offered by the Rev. R. G. Brant, D.D.

The report of the Committee of Arrangements, including the announcement of receptions and special invitations to excursions and entertainments, was then made.

The Secretary read the following

REPORT OF THE COMMITTEE ON NOMINATIONS,

signed by P. O. Hooper, of Arkansas, Chairman, and William Wile, of Connecticut, Secretary.

President—E. H. Gregory, St. Louis, Mo.

Vice-Presidents—First, B. H. Miller, Stillwater, Minn.; *Second*, W. B. Welch, Arkansas; *Third*, William H. Pancoast, Philadelphia; *Fourth*, William C. Wile, Connecticut.

Permanent Secretary—William B. Atkinson, Philadelphia.

Assistant Secretary—J. Nevins Hyde, Chicago.

Treasurer—Richard J. Dunglison, Philadelphia.

Librarian—C. H. A. Kleinschmidt, Washington, D. C.

Committee on Necrology—J. M. Toner, Washington, D. C., Chairman.

Judicial Council—N. S. Davis, Illinois; H. Brown, Kentucky; William Brodie, Michigan; D. J. Roberts, Tennessee; R. C. Moore, Nebraska; T. A. Foster, Maine; James A. Gray, Georgia.

Trustees of the Journal of the American Medical Association—P. O. Hooper, Arkansas; Alonzo Garcelon, Maine; L. S. McMurtry, Kentucky.

NEXT PLACE OF MEETING, CHICAGO, ILL.,

and the time the first Tuesday in June, 1887.

Chairman of Committee of Arrangements—Charles G. Smith.

OFFICERS OF SECTIONS,

nominated by the Sections and elected by the Association.

Practice of Medicine—J. S. Lynch, Baltimore, Chairman; J. B. Martin, St. Louis, Secretary.

Obstetrics and Diseases of Women—F. M. Johnson, Kansas City, Chairman; W. W. Jaggard, Chicago, Secretary.

Surgery and Anatomy—H. H. Mudd, St. Louis, Chairman; John B. Roberts, Philadelphia, Secretary.

Ophthalmology, Otology, and Laryngology—X. C. Scott, Cleveland, Chairman; J. H. Thompson, Kansas City, Secretary.

Diseases of Children—De Laskie Miller, Chicago, Chairman; W. B. Lawrence, Batesville, Ark., Secretary.

Oral and Dental Surgery—John S. Marshall, Chicago, Chairman; E. S. Talbot, Chicago, Secretary.

State Medicine— —— ——, Chairman; W. Wyman, New York, Secretary.

Dr. A. L. Gihon read

THE REPORT OF THE COMMITTEE ON PRESIDENT'S ADDRESS,

signed by John H. Murphy, of St. Paul, Chairman, and by A. Garcelon, of Maine. First, in their opinion, it was proper and desirable that this Association should without delay memorialize Congress in behalf of appointing a scientific commission consisting of three to visit the habitats of yellow fever and determine the value and the claims of Drs. Carmona and Freire, who maintain that they have discovered means of preventing attacks of the disease. Second, the committee were

NOT AGREED CONCERNING THE SUGGESTION OF THE PRESIDENT TO DISPENSE WITH THE USE OF THE METRIC SYSTEM.

Third, the committee heartily approved of the suggestion that the Association should establish a Section on Dermatology and Syphilis. Fourth, the committee endorsed the suggestion of the President that the

SECTIONS SHOULD ELECT THEIR OWN OFFICERS,

and were further of the opinion that the efficiency of the sections would be enhanced by the continuance in office of their respective secretaries. Fifth, the view that the papers read before the Association were its exclusive

property was endorsed. Sixth, that the Association should emphatically

DENOUNCE THE ENDORSEMENT, BY CERTIFICATE, OR ADVERTISEMENT, OR TESTIMONIAL, OR BY ANY FORM WHATSOEVER, OF PROPRIETARY REMEDIES

and appliances, and it should instruct the Judicial Council to take action in all such cases without the formal presentation of charges, and that it should be regarded as a stigma to endorse the use of such proprietary means for the relief and cure of disease. Seventh, that it is desirable that the Association should appoint a committee at this meeting, to consider the advisability of changing the organic law, by establishing branches or by some other plan, and to report at the next annual meeting. Eighth, they earnestly re-echo the wish of the President that the members of the profession will cordially co-operate

TO MAKE THE NEXT INTERNATIONAL MEDICAL CONGRESS ATTRACTIVE

and instructive to the foreign members, sacrificing personal and private piques and disappointments to contribute to that success which has been unconditionally pledged in the invitation extended to the Congress to meet in the United States in 1887.

The report of the committee was adopted.

Dr. N. S. Davis, Chairman, made the report of the Standing Committee on Meteorological Conditions and their Relations to the Prevalence of Diseases. Also concerning the subject of collective investigation in co-operation with the committee of the British Medical Association. The answers received to blanks already sent out would form the basis of a report at the next annual meeting, and also at the Ninth International Medical Congress.

Dr. J. M. Keller, Chairman, made a special

REPORT ON CREMATION,

in which reasons were given why fire should be substituted for earth burial with the following resolution: "That cremation has become a sanitary necessity in all highly populated cities, and this Association advises its adoption so far as practicable."

The report was also signed by Dr. Logan, of New Orleans.

The report was adopted. The vote by which it was adopted was, on motion by T. A. Reamy, of Cincinnati, reconsidered. The report was then referred to the Section on State Medicine.

Dr. John B. Roberts, of Philadelphia, moved that the Secretary of the Association be instructed to give official information why the report of the Judicial Council upon his table yesterday was not read at that time.

The President ruled that it was out of order, because the Judicial Council would soon report.

Dr. Roberts appealed from the decision of the Chair, and the decision of the President was sustained on a rising vote.

Dr. Toner presented the following resolution: "Resolved, That the Association be requested to return to the Judicial Council the report in the case of the Philadelphia County Medical Society, for the purpose of hearing additional testimony, and all parties interested be requested to appear before the Council now in session."

The resolution was adopted.

Dr. J. T. Whittaker, of Cincinnati, then delivered the

ADDRESS OF THE CHAIRMAN OF THE SECTION ON PRACTICE OF MEDICINE.

There are three planes in the history of medicine: First, the study of the symptoms or appearance of disease; second, the observation of the effects or lesions of disease; third, investigation into the cause of disease. The etiology of acute infections is comprised under the single term, bacteriology, for it has now been demonstrated that pathogenic micro-organisms do exist beyond dispute in distinct and definite entity. The speaker then considered the theory of spontaneous generation, the claims of convertibility of all germs, the question of mutability or immutability, the deviations that do occur, the doctrine that the germ, not the form, is essential, the morphology of bacteria, the destruction of bacteria, the formation of zoöglea, the subject of pure culture-soils, the necessities with reference to temperature and the need of oxygen, the fecundity of micro-organisms, the topic of spores and saprophytes, the mode of invasion and dissemination, the effects upon the tissues, their presence in neoplasms, in giant cells, in the blood. The question of immunity was studied, and also the manner in which micro-organisms, produce the phenomena of disease. The address concluded with a brief reference to the subject of ptomaines.

Dr. John H. Rauch, of Springfield, Ill., then delivered the

ADDRESS OF THE CHAIRMAN OF THE SECTION ON STATE MEDICINE,

in which he first defined State medicine and the branches of science which it included. He agreed with Richardson, who says of the so-called science and art of preventive medicine, "It is not a science, it is not an art, separated necessarily or properly from so-called curative medicine; on the contrary, the study of prevention and cure proceed well together. And he is the most perfect sanitarian and he is the most accomplished and useful physician who knows most, both of the prevention of disease and of the nature and treatment of disease. He who knows, in fact, the before and the after of each striking phenomenon of disease that is presented for his observation." To the above Dr. Rauch would add Dr. H. A. Johnson's conclusion, that it is the duty of the State to protect its citizens from the injuries they may sustain from the practice of incompetent physicians and surgeons, as well as from any other source of danger to public health. State medicine may, therefore, be now defined as the connection of the State with that branch of science which relates to the prevention, cure, or alleviation of the diseases of the human body. It embraces not only all public sanitary measures, but also the practice of medicine in so far as this is regulated by the State.

The first topic considered was the regulation of medical practice, which also and necessarily included the subject of medical education. The author then set forth the authority by which the State assumes to regulate the practice of medicine. It rests in the inherent and plenary power which resides in the State to promote all things helpful to the comfort, welfare, and safety of society. An unbroken line of authorities, from Blackstone down to the most recent decisions of the various Supreme Courts, hold that the police powers of the State are plenary and inalienable, co-extensive with the natural right of self-protection, that their exercise is demanded and justified by the law of overruling necessity, and that broadly they are the foundation of all laws and regulations for the well-being or government of the people, and specifically, of all laws, ordinances, rules, and regulations for the preservation of the health or safety of the community. A sketch of the legislation which has been done in this direction was then given, beginning with 1859, when North Carolina made a law creating a State Board of Medical Examiners. The general drift and tendency of this legislation are toward securing a recognized standard of professional attainments, evidence of which is afforded by the presentation of a diploma, of graduation from some legally chartered institution in good standing, or, in the absence of this, an examination more or less strict in the various fundamental branches of medical science. The exceptions are in the States of Alabama, Mississippi, North Carolina, and Virginia, where the diploma is ignored. A low standard of medical education, and the absence

of uniform legal requirements are responsible almost exclusively for the overcrowding of the profession. It was within bounds to say that the excess of the percentage of new graduates over the percentage of increase of population represents the number of unnecessary recruits to the ranks of the profession every year. Exclusive of the sessions of 1885–86, there were 106,947 physicians in the United States, and there had been an annual increase of over five and one-half per cent., while the population had annually increased in less than two per cent. As a matter of personal interest, he had followed up the careers of 789 out of 1,000 physicians who studied four years and attended three terms before graduating. These, with but few exceptions, were the successful and prominent members of the profession in the different communities in which they reside.

Dr. Rauch reached the following conclusions: First, that the best interests of the public welfare demand the highest attainable standard of educational qualification, skill, and ability among those engaged in the practice of medicine; second, that it is the duty of the State to exercise the inherent plenary power and authority which it possesses for the protection and promotion of the public welfare to secure such standard; third, that uniform State laws, exacting of every one aspiring to practise medicine proof of personal fitness and professional competency in improving the standard of medical education, and in enhancing the dignity and usefulness of the medical profession. Specifically he suggested that the Association should put itself upon record at this meeting as recommending the extension of the period of study to four years, and of attendance upon lectures to three full terms, with ample hospital practice and clinical instruction as the requirements for graduation in medicine. To this end he urged that the Committee on State Medicine be instructed to frame a law for the regulation of the practice of medicine, which law, when endorsed by the Association, shall be the standard with which all existing legislation on this subject should be made to conform as speedily as practicable, and which shall be urged for adoption by those States where no such law now exists

The second part of the address was on the advances and discoveries in preventive medicine, which referred to boards of health, branches of national service, and to what has been done in this department abroad.

Dr. A. Y. P. Garnett, of Washington, offered the following resolution, which was adopted: "That the delegates to this Association be requested, on returning to their homes, to adopt such means as may to them seem best to call the attention of their respective representatives in the Congress of the United States to the

DESIRABILITY OF MAKING AN APPROPRIATION OF MONEY TO ASSIST IN HEARTILY RECEIVING AND ENTERTAINING THE INTERNATIONAL MEDICAL CONGRESS IN 1887.

The Treasurer's Report was read and accepted, and referred to the Committee on Publication.

The Librarian's Report was read, and contained the recommendation that the sum of $10 be appropriated to subscribe for the "Index Medicus" for 1886. The report was referred to the Committee on Publication, and the recommendation adopted.

The report of the Committee on Publication was made the special order for Friday morning.

Dr. A. L. Gihon, of Washington, offered an amendment providing for a Section on Dermatology and Syphilis. Laid over for one year.

Dr. Gihon offered the following, which was adopted: "That a committee of nine, including the president-elect and the four vice-presidents-elect, be appointed by the Chair to consider various propositions looking toward amendment of the organic law of the Association by establishing branches, or in any other way, if any change may be deemed desirable, and to report at the next annual meeting." The Association then adjourned to meet Friday morning at ten o'clock.

Friday, May 7th—Fourth Day.

The Association was called to order by the President. Prayer was offered by the Rev. W. V. Tudor, D.D.

The Secretary announced the officers of the Section on Medical Jurisprudence: Isaac N. Quimby, Jersey City, Chairman; H. H. Kimball, Minnesota, Secretary.

GENERAL WILLIAM T. SHERMAN

was discovered seated in the audience, and amid tremendous cheering was called to the platform, from which he made a few exceedingly appropriate and complimentary remarks, including the statement that he had seen much of the surgeons of the United States, and believed that the medical profession in America ranks among the highest and in favorable comparison with the physicians and surgeons of the whole civilized world.

Dr. C. K. Mills, of Philadelphia, moved that the order of business be suspended for the purpose of receiving the report of the Judicial Council.

Dr. J. B. Hamilton moved to lay upon the table. Carried.

Dr. J. M. Toner reported from the Board of Trustees of the *Journal*, including the report of the editor, which was read by Dr. Davis. The *Journal* has a total weekly edition of 4,271, of which 3,276 are for members of the Association. There has been a net decrease of expenses. The small increase of subscribers was attributed to the dissatisfaction on the Code caused by the State of New York, and the unfavorable criticisms on the organization of the International Medical Congress. Dr. Davis has consented to remain editor of the *Journal*.

Dr. Garcelon, of the Auditing Committee, reported that the accounts of the Treasurer were correct.

Dr. J. M. Toner reported for the Judicial Council that the delegates from the Tristate Medical Society were not entitled to registration, that the delegates from the Davidson County Medical Society, Tennessee, were entitled to registration, that the protest against the delegates from the Mississippi Valley Medical Association had been dismissed, that the registration of W. W. Dixon had been granted, that the matter of the Philadelphia County Medical Society had been referred back with all the papers to the society from which the delegates came for adjudication.

Dr. Jackson, of Philadelphia, asked the President to rule on the status of the delegates who had registered, and whose dues had been received on the credentials presented.

The President ruled that it was out of order, as the decision of the Council was final.

The report suggested the return of the dues received from the delegates who had registered.

Dr. Eugene Smith, of Detroit, delivered the address of the Chairman of the Section on Ophthalmology, Otology, and Laryngology, in which he gave a brief summary of what had been done in these departments during the last year, making mention of transplantation of the eye, intubation of the larynx, laryngeal photography, etc. The address was brief, concise, and comprehensive.

Dr. W. D. Haggard, of Nashville, delivered the address of the Chairman of the Section on Diseases of Children, which was a plea for the better recognition of the importance of diseases of children.

Dr. John S. Marshall, of Chicago, delivered the address of the Chairman of the Section on Oral and Dental Surgery, which consisted of three parts, read by title: first, "Transplantation of Teeth in Artificial Aveoli;" second, "Sponge Grafting in the Mouth;" third, "Staphylorraphy in Early Infancy."

Dr. J. M. Toner, Chairman, formally presented the report of the Committee on Neurology, which from time

to time had appeared in the *Journal* of the Association.

The Section on State Medicine reported the following resolutions, which were adopted: That the Association reaffirm its utterances on the use and abuse of alcohol, and recommend the study of hygiene in our public schools; that a committee be appointed to consider the subject of cremation, and report at the next annual meeting; that the Association direct the Section on State Medicine, to prepare and report a form of law regulating the condition requisite to beginning the study of medicine, the requirements of graduation, etc.

The Committee of Arrangements were instructed to place the report of the Committee on Publication on the programme for the first day's proceedings at the next annual meeting.

Dr. John B. Roberts, of Philadelphia, offered a series of resolutions, asking the President and Secretary for information as to why the report of the Judicial Council, laid upon the Secretary's table yesterday and seating the delegates for the Philadelphia County Medical Society, was not read.

On motion by Dr. Octerlony, of Louisville, they were laid upon the table.

The President appointed a committee of nine, consisting of the President, President-elect, four Vice-Presidents-elect, and Drs. N. S. Davis, A. L. Gihon, and J. M. Toner, to report at the next annual meeting with reference to change in the organic law of the Association establishing branches, etc.

DELEGATES TO THE BRITISH MEDICAL ASSOCIATION:

N. S. Davis, Chicago; B. W. Dawson, Cincinnati; D. McLean, Ann Arbor; E. Smith and W. Brodie, Detroit; B. A. Watson, Jersey City; W. T. Briggs, Nashville; W. H. Pancoast and J. V. Shoemaker, Philadelphia; L. H. Montgomery, Chicago; E. Cutter, New York; G. C. Gordon, Portland, Me.; J. C. Cattell, Ontario Medical Association; H. O. Walker, Detroit.

Delegate to Canada Medical Association, W. Brodie, of Detroit.

Dr. John B. Roberts resigned as Secretary of the Section on Surgery and Anatomy. Accepted. The Chairman of the Section was authorized to fill the vacancy.

Dr. Baldwin, of Illinois, moved that the resolution introduced by Dr. Roberts reflecting upon the President and Secretary be expunged from the records. Adopted under the previous question.

Dr. Jackson, of Philadelphia, offered a

PROTEST AGAINST THE ACTION OF THE JUDICIAL COUNCIL, BY WHICH THE PHILADELPHIA COUNTY MEDICAL SOCIETY HAD BEEN DENIED REPRESENTATION AT THIS MEETING,

signed by Drs. C. K. Mills, J. B. Roberts, and others. Laid upon the table.

Drs. J. B. Johnson, N. S. Davis, and W. M. McPheeters were appointed a committee to conduct Dr. E. H. Gregory, President-elect, to the chair.

Drs. N. S. Davis and A. Garcelon introduced a general resolution of thanks to all in St. Louis for the cordial reception and most hospitable entertainment of the Association.

Dr. Keller offered an amendment to the by-laws that officers of sections be nominated by the Nominating Committee. Laid over until next year.

Complimentary and appropriate remarks were made by President-elect Gregory, and by President Brodie, and the Association adjourned to meet in Chicago on the first Tuesday in June, 1887.

Nineteen Russians and One Wolf.—It quite passes American comprehension to understand how one mad wolf was able, within forty-eight hours, to bite nineteen adult Russians, as is reported in *Le Progrès Médicale*. The wolves of Russia, when mad, must be very mad indeed.

SECTION ON PRACTICE OF MEDICINE.

Dr. J. F. Whittaker, of Ohio, Chairman; Dr. B. L. Coleman, of Kentucky, Secretary.

Tuesday, May 4th—First Day.

The first paper was

ETIOLOGY OF DUELAST,

by Albert C. Haven, of Illinois, in which the author reached the conclusion that it was an uncertain quantity.

The next paper, by Dr. Frederick N. Huston, of Rockland, Me., was entitled

THE EFFECTS OF CERTAIN PHILOSOPHICAL PRINCIPLES THAT HAVE NOT BEEN NOTICED, IN AID OF THE CIRCULATION OF THE BLOOD.

The writer assumed that the circulation of the blood is not so well understood that light would not be acceptable. He proposed to treat the subject in the light of certain philosophic principles self evident facts that need no demonstration from experiment. He took for his text the subject of cohesion, and quoted from a statement in "Reference Handbook of the Medical Sciences," vol. i., page 565, "Blood has greater cohesion than water," and stated that viscidity is a quality of all liquids, expressed in different degrees. It is greater in blood than water. While cohesion amounts to the same thing as a physical force, holding together particles of matter, viscidity and cohesion resemble each other. He claims there is no difference to the cohesion of liquids. It is a peculiar property whereby they resemble solids when acted upon by excentric forces. The venous system is compared to a cone, with apex at the heart and its base represented by the periphery of the body. It might also be said that its base is connected with that of another cone similarly representing the arterial system.

He stated that each contraction of the ventricles is a force exerted with the same, if not greater, effect on the venous circulation, as on the arterial through cohesion. Whatever may be the effect of valves in the inferior veins toward relieving gravity on the lower vessels, it must be remembered there is another column of blood without valves pressing downward with all the force of gravity as well as that of the arterial wave. If these lower vessels were compelled to sustain a pressure it is easy to see what the effect would be. Fortunately the force acting throughout the venous cone, reaching even the arterial wave, so far unloads the inferior vessels that the effect of gravity, during the interval this force is at rest, can do no more than fill these vessels to the normal tension.

The paper was a very exhaustive and scientific one, and in addition referred to topics such as the explanation of the untoward effects of hypodermic injections, syncope from chloroform, the action of nitrite of amyl, etc.

Dr. Brenner, of St. Louis, read a paper on

ESSENTIAL VERTIGO.

It was discussed by Dr. A. B. Arnold, of Baltimore, and others.

Dr. O. T. Shultz, of Mt. Vernon, Ind., read a paper on

THE USE OF SO-CALLED ANTIPYRETIC DOSES OF QUININE IN TYPHOID PNEUMONIA.

The paper was lengthy and exhaustive.

Wednesday, May 5th—Second Day.

The first paper was read by Dr. S. S. Laws, of Columbia, Mo., President of the Missouri University, on

THE LIFE AND LABORS OF LOUIS PASTEUR.

The labors of the great scientist were sketched with reference to their bearings upon the discovery of the true nature and the treatment of diseases in plants and animals. The diseases in the vegetable kingdom, as in the

case of vinegar, wine, beer, the potato, etc., have been traced to living organisms as their causes; the diseases of the silkworm, of fowls, of swine, of sheep, of cattle, and of other animals, which diseases have various technical names, have in like manner been traced to microbes, or microscopic living beings, and naturally enough this line of investigation and discovery has penetrated the dark and mysterious domain of human diseases. Infinitely minute living organisms, as the actual cause of some of these diseases, formerly attributed to the spontaneous peccancy of the humors of the body, have been certainly discovered, and also the rational means of combating them. The views presented were guarded against exaggeration and misconception, and it was not claimed that the conquest is completed, but that it is valiantly begun, and that, in the following strong language of Professor Tyndall, in a letter to M. Pasteur, to wit, "for the first time in the history of science we are enabled to entertain the sure and certain hope that, in relation to epidemic disease, medicine will soon be delivered from empiricism and placed upon a real scientific basis. When this great day shall come, humanity will recognize that it is to you (Pasteur) the greatest part of its gratitude is due."

Dr. Philip Zenner, of Cincinnati, read a paper entitled,

VALUE OF THE KNEE PHENOMENON IN THE DIAGNOSIS OF DISEASES OF THE NERVOUS SYSTEM.

This phenomenon has been known to the profession since the simultaneous publications of Erb and Westphal in 1875. Its clinical significance is attached to the fact, pointed out by Westphal in his earliest publication, that it is present in health and is absent in cases of locomotor ataxia, usually disappearing at the very commencement of the disease. It may also be absent in anterior poliomyelitis and neuritis, when the lumbar portion of the spinal cord or its nerves are the seat of disease. It may also be absent in many cases of diabetes mellitus, and is sometimes temporarily abolished in chronic alcoholism, and after attacks of diphtheria.

Various examinations have been made to determine whether it is absent in health. Berger missed it in 22 out of 1,409 healthy men, Eulenberg in 4.8 per cent. of healthy adults and five per cent. of children, Bloch in 5 out of 694 school children; Polizans examined 2,404 school children, at first missed it in 6, but finally obtained it in every one. Jendassik examined 1,000 persons chiefly adults, not suffering with nervous diseases and elicited the phenomenon in all but one, a case of diabetes mellitus.

The author then gave his own observations, which had embraced the examination of 2,106 persons, all of whom were adults, and chiefly males. Of these 1,174 were inmates of various insane asylums; the others, excepting 106 in the medical wards of the city hospital, were mostly in apparent health. Of this number the knee phenomenon was abolished in 28, of whom 5 had fully developed locomotor ataxia, 12 were in the earlier stages of the same disease, while 11 manifested no other symptom of disease of the cord.

The cases of insanity were treated of separately, because Westphal had shown that, in such cases, the absence of this phenomenon, even when there are no other symptoms, is strong presumptive evidence of disease of the posterior columns of the cord, and because of its special value in diagnosing the form of insanity. Of the 28 cases of insanity with abolished knee phenomenon, 10 were cases of general paralysis, and in 2 it was doubtful whether there was general paralysis or not, notwithstanding the fact that there were at that time very few cases of general paralysis in the asylum. In many cases of general paralysis and locomotor ataxia we have reflexing rigidity of the pupils, they do not respond to light. In 4,000 insane, 492 had rigidity of the pupils, eighty-five per cent. of whom had general paralysis. Nine out of ten of the essayist's cases of general paralysis had pupil symptoms, one out of the two doubtful cases, and only two out of the eleven other cases. Absence of knee phenomenon and presence of refractory rigidity of the pupils are of great assistance in diagnosing obscure cases.

In 932 sane persons the knee phenomenon was found in 5. The fact that the phenomenon is absent in other pathological conditions does not lessen its significance in locomotor ataxia, for the other conditions can be easily differentiated. In the author's experience it is not so often absent in diabetes mellitus as some observers believe. Rosenstein missed it in 6 out of 9 cases and Bouchard in 19 out of 66; the author found it present in all. He did not think it often present in chronic alcoholism. He had examined quite a number of cases in the city hospital, and 404 men at the Workhouse, who were many of them hard drinkers. Strychnia restores it in chronic alcoholism, but does not in locomotor ataxia.

The author then spoke of the method of eliciting the knee-jerk. After careless examinations it is often said to be absent when it can be readily elicited. The ordinary method will answer in most cases, but in some it will not. Should it fail, the person should sit upon a table, with the legs dangling and the knees entirely exposed, and the ligament be struck in every part. In a small number there will still be failure by this method. For such cases Jendrassik has recently pointed out another method. The patient is seated as above, and, while the examiner strikes upon the ligament, he is requested to link the bent fingers with one another, and pull as hard as he can. This augments the muscular tonus and the response increases. This method has enabled the author to find it in a number of cases which did not respond before. So great was the difference that the author thought he might find it in some cases of locomotor ataxia, but failed. In some of his cases the response, though present, was so slight that it might be pathological.

Is the phenomenon always absent in locomotor ataxia? Westphal says yes, in typical cases, but present whenever the disease affects the posterior columns in the lumbar region, which occurs usually at an early period. Later writers have reported cases with post-mortems where it was present. This, however, is so rare as to be of little significance. The essayist had never seen it absent but once, and in this case the appearance was rather that of a diffuse myelitis than of a systemic disease of the cord. He had a number of cases under observation at present where the phenomenon was abolished on one side and difficult to elicit, but these were all still in the earlier stages of the disease.

The paper was discussed by Drs. A. B. Arnold, of Maryland, X. C. Scott, of Ohio, and Dr. Colhet, of Missouri.

Dr. Joseph Jones, of New Orleans, read a paper on

SOME PRACTICAL OBSERVATIONS ON THE RESULTS OF MEDICAL TREATMENT IN THE CHARITY HOSPITAL, NEW ORLEANS, DURING THE YEARS BETWEEN 1869 AND 1886.

The paper referred largely to malarial fever and its treatment.

Dr. A. F. Potter, of Boston, read a paper on "Potassium Chloride," in which he spoke of its value in pelvic cellulitis in doses of ten grains every three or four hours. In epilepsy he has found it even more valuable than the bromide of potassium, and gives it three or four times daily. He had never used it in goitre.

Dr. John A. Octerlony, of Louisville, Ky., read a paper on the "Clinical Aspects of Renal Cancer," which was well illustrated with charts, and referred particularly to the differential diagnosis between this and other diseases with similar features.

The Section adjourned to meet on Thursday.

THURSDAY, MAY 6TH—THIRD DAY.

DR. HERBERT F. WILLIAMS, of New York, read a paper on

PNEUMATIC DIFFERENTIATION,

and gave demonstrations with the pneumatic cabinet.

The discussion was opened by E. F. Ingals, of Chicago, and continued by the Chairman and others.

DR. F. H. PATTEN, of Dayton, O., read a paper on

PNEUMONIA IN THE OLD.

This was followed by one on

THE ETIOLOGY OF DENGUE,

by J. W. MCLAUGHLIN, M.D., of Austin, Texas.

The epidemic of dengue which prevailed throughout the State of Texas during the fall of 1885 was unusual in many respects; for example, first, in its universality; second, in the violence of its symptoms; third, in its manifest contagiousness; fourth, in its protracted convalescence of its subjects; fifth, in its hemorrhagic tendencies; and, sixth, in its numerous sequelæ. Many cases where direct contagion was the cause came under the observation of the writer. There can be no doubt that by this means it was carried and spread from one neighborhood to another, and from the city to the country by infected individuals. It would seem from the peculiar clinical history of dengue and its epidemic character, that it is a specific disease, that micro-organisms are the source of its infection, and that these micro-organisms find in the blood a suitable environment for their growth and multiplication. In order to determine the correctness of this theory, and, if possible, to obtain information with reference to the etiology and pathology of this malady, especially as medical literature is silent upon these matters, the following investigations were made: First, blood was obtained from living subjects during the various stages of dengue, and microscopically examined directly, *i.e.*, without the addition of chemical reagents. Second, after treatment with such agents, viz., glacial acetic acid with and without dilution, caustic potash in strong and weak solutions, chloroform, and ether, third, the blood was dried upon sterilized cover-glasses and subjected to the action of the various staining agents. Fourth, dengue, blood obtained from living subjects was introduced into test-tubes containing sterilized culture-media prepared for this purpose; these were closed with sterilized cotton plugs and kept at a temperature of 100° F. for the growth and multiplication of those organisms which were contained in the blood. Fifth, blood was drawn directly from the veins of a dengue subject into a series of sterilized glass bulbs, united by a capillary glass tube. This was done in such a manner as to effectually guard against the introduction of all foreign germs. The series of bulbs were then put into an incubator and kept at 100° F. Sixth, the matters vomited and urine passed by dengue subjects were microscopically examined. The following are the results obtained: In the blood examined directly or after treatment with the chemical agents named, stained or unstained, he found, often in great numbers, in the cell elements as well as in the plasma, micrococci spherical in shape and red or pinkish in color, often surrounded by gelatinous capsules. He always succeeded in growing in culture-tubes, upon the surface of the jelly, micrococci, and no other form of bacteria, which in size, color, shape, and behavior are identical with those seen in fresh dengue blood. The blood contained in the series of glass bulbs was examined, the first bulb at the expiration of six weeks, the other after three months. He found the blood to contain a pure culture of micrococci which in all respects were identical with those previously seen in fresh blood and grown upon culture-jelly. These organisms were also seen in the matters vomited in certain malignant cases of dengue which were characterized by much gastric catarrh, and also in the urine passed. In a very few cases he found this to contain casts of the uriniferous tubes, which were composed of these organisms held together by their gelatinous envelopes, at the end of these casts, where they were less firmly attached or cemented together. The shape, size, and color of the micro-organisms were found to correspond with those seen in the blood or grown upon the jelly. The blood used in these examinations was obtained from many different individuals at different times and places and during the various stages of dengue. It would seem evident that if spherical bodies, uniform in size, shape, color, and behavior are found in the blood in certain pathological conditions, and that these bodies can resist the destructive action of glacial acetic acid, caustic potash, chloroform, and ether, that these must be micrococci, inasmuch as all the blood-cells and granules are destroyed by these chemicals.

Sterilized cover-glasses upon which dengue blood had been dried were subjected to the action of many aniline dyes, to obtain, if possible, one for which these micrococci have an elective affinity. After many trials and failures he succeeded in staining the organisms with methyl blue in a solution of caustic potash in a permanent manner. These micro-organisms were uniformly found in the blood of about forty cases of dengue, the number from which blood was obtained. No doubt they would have been found in other cases if looked for. In every instance tubes inoculated showed, upon the surface of the jelly at the point of inoculation, a white spot elevated above the surface. When a small amount of this was examined under a high power, it showed invariably a pure culture of micrococci which in every respect are identical with those found in dengue blood. The uniformity of these results in growing pure cultures of dengue micrococci certainly indicates that the matter of inoculation came from a common source, *i.e.*, the blood.

A paper on "Meconeuropathia," by C. H. Hughes, of St. Louis, was read by title, as was one on "Laws Determining Sex," by Robert Funkhouser, of St. Louis.

SECTION IN SURGERY.

TUESDAY, MAY 4TH—FIRST DAY.

NICHOLAS SENN, OF MILWAUKEE, CHAIRMAN; H. H. MUDD, OF ST. LOUIS, SECRETARY.

The Secretary read a paper sent by WILLIAM M. MASTIN, of Mobile, on

VENOUS BLOOD TUMORS OF THE CRANIUM IN COMMUNICATION WITH THE INTRACRANIAL VENOUS CIRCULATION, ESPECIALLY THE SINUSES OF THE DURA MATER.

It contained the following propositions: Cranial venous blood tumors are to be classified into three types, 1, congenital, spontaneous, and traumatic; 2, these types are divided into the diffuse, the venous, or the vascular, in which the tumor is formed at the expense of the coats of the veins; 3, the venous type is most common, and of this type the diffuse is the rarest of all varieties; 4, the diffused variety is especially characteristic of the spontaneous and also of traumatic bruises. The venous type occurs most frequently congenitally. General surgical interference is not called for. When, however, operative interference is deemed proper, it may be for either the diffused or the varix. Exposure and ligation of the pedicle, or, if necessary, delegation in its course, the trephine being employed only to furnish the required space. Lateral ligation and section were preferred to complete ligature. For tumors composed of varicose vessels the electro-puncture or strangulation of the veins may be adopted, with preference for the former.

DR. MOSES GUNN, of Chicago, read a paper on

THE VALUE OF AN ATTEMPT AT ENUCLEATION IN A NEUROMA

which seems to demand resection of the nerve. The case was one in which a neoplasm involved the ulnar

nerve. Enucleation was followed by relief from pain, but the symptoms all returned at the end of four months.

Dr. B. A. Watson, of Jersey City, read a paper on spindle-celled sarcomas, and reported a case and presented the specimen.

Dr. Joseph Ransohoff, of Cincinnati, presented a paper on the

TREATMENT OF THORACIC ANEURISM

by the introduction of wire, with the report of a case.

Dr. W. P. Verity, of Chicago, was announced to exhibit

A SURGICAL ENGINE.

The Section then adjourned to meet Wednesday.

Wednesday, May 5th—Second Day.

Dr. Maclean, of Michigan, read a volunteer paper giving an account of

A SUCCESSFUL CASE OF AMPUTATION AT HIP-JOINT.

Drs. Logan, of Louisiana, Dawson, of Ohio, and Staples, of Minnesota, reported somewhat similar cases, and discussed to some extent the comparative indications for amputation and laparotomy.

Dr. J. McF. Gaston, of Georgia, read the next paper, entitled

SURGICAL RELATIONS OF THE ILEOCÆCAL REGION.

He designed by his title to include all the conditions calling for surgical interference in the ileocæcal region. There are two classes of such troubles, viz., those in which there is a degeneration of tissue in immediate relation with the cæcum and colon, which may result in malignant growths pressing upon and interfering with the function of the intestine, or there may be suppurative inflammation forming sinuses in all directions, and bursting through, either externally or into the bowel, may set up a long train of sequelæ by extension of inflammation to the adjacent tissues, or septic influences may be introduced and greatly aggravate the trouble, especially in cases of women. Sutton, in *The Lancet*, advanced the view that inflammation is not essentially pathological, but is reparative, and only becomes pathological when it is excessive. It may be simple or specific, and bacteria are destroyed by inflammatory action according to his view. Modern opinions in regard to laparotomy are far different from what they were a few years ago. In Germany surgical procedures in cases of ileocæcal trouble are generally too long delayed, still he holds that there can hardly be a grosser error than to adopt the position that such affection always demands surgical operation. Statistics show that less than ten per cent. of cases with invagination recover. He favors exploratory incision, and active procedures for the relief of obstruction, etc. He summed up his results with the following conclusions, viz.: 1, Certain forms of such trouble are sometimes spontaneously corrected; 2, in cases of extra-peritoneal inflammation and suppuration, puncture and incise; 3, in case of disorders involving the peritoneum, incise and explore; 4, when there is a stenosis or a malignant growth, ileocolostomy is to be performed; 5, gangrenous portions should be resected; 6, operative measures, if demanded at all in the ileocæcal region, should not be delayed, but performed at once.

THE COMMITTEE ON HONORABLE MENTION,

consisting of Drs. Logan, of New Orleans, Gunn, of Chicago, and Staples, of Minnesota, appointed by the Chairman on Tuesday, reported that only one paper had been submitted, and that, in the opinion of the Committee, did not merit the mention.

A discussion on the proper

TREATMENT OF PENETRATING WOUNDS OF THE ABDOMEN

was introduced by Dr. Henry H. Smith, of Philadelphia, who was followed by Drs. B. A. Watson, of Jersey City, and E. H. Gregory, of St. Louis, the appointed disputants. The volunteers were Drs. H. O. Marcy, of Boston, John B. Hamilton, of the Marine Hospital Service, Byrn, of Illinois, Kinloch, of South Carolina, and Jennings, of Arkansas, the discussion being formally closed by Dr. Gaston. Drs. Watson, Marcy, Hamilton, and Kinloch favored the aggressive mode of treatment —exploratory incision, arrest of hemorrhage, and careful aseptic cleansing and closing of the wound.

Dr. Gregory strongly urged a more conservative policy, and said never open the belly unless it is evident that some of the viscera have been wounded. The condition of the patient must determine the question of operation. Do not operate until it is demanded. He regards exploratory incision as justifiable only in extreme cases, not simply to find out what is the matter. If the operation were not so easy of performance, attended with so little immediate danger, and so brilliant in the impression produced, he thought that laparotomies would be made much less frequently than they have been of late years. He favors Listerism on account of rigid cleanliness—accepted methods without committing himself to the theories of antiseptic surgery.

Dr. Hamilton related some interesting cases, tending to show the advantage of immediate interference in all cases of penetrating abdominal wounds. He recognized the danger of laparotomy, and thought we should not expect as good results in treating gunshot wounds as after simple laparotomies, but he urged immediate interference, or as soon as possible after receipt of wound.

Dr. Jennings related a very interesting case, where the whole intestines gushed out through a wound of the abdominal wall, were washed with simple saline solution, a rent three-quarters of an inch long was closed with five interrupted sutures, and the patient made a complete recovery, and lived for years after.

Dr. Edmund A. Andrews, of Chicago, read a paper on

DIGITAL EXPLORATION OF LUMBAR ABSCESS,

in which he advocated opening such abscesses freely, so as to allow the introduction of the finger for the purpose of thorough exploration. His practice is to make counter openings and wash out the abscesses and sinuses with antiseptic solutions. He read only two cases of the nine which he had reported in his paper. Some cases of lumbar abscess recover after simple aspiration and washing out the cavity with antiseptic solutions. If this fails or is inapplicable by reason of the abscess having been already opened when coming under treatment, free incision and washing out with antiseptic solution should be resorted to at once. Modern treatment, aspiration, and antiseptic injections had exploded the old notion that it is a dangerous affair to open and evacuate the pus from such abscesses.

Dr. Byrd, of Illinois, said he heartily agreed with the views of Dr. Andrews. He desired simply to call attention to what he considered the very

BEST ANTISEPTIC INJECTION,

an agent which he had been using for some months with great satisfaction, viz., the peroxide of hydrogen, which would destroy and remove every particle of pus. It would also give the advantage of hyperdistention by the formation of gas in the cavities.

Dr. C. H. Finger, of Illinois, regards lumbar abscesses as simply symptoms, and does not think that simple evacuation of the contents can be regarded as good surgical treatment. It should be the aim of the surgeon to remove the cause.

Dr. E. R. Lewis, of Missouri, asked what means there are for early diagnosis of these cases.

Dr. Hamilton, of Ohio, said that in many years of practice and teaching he had found no other so common evidence of incompetency and inefficiency among practitioners as the frequent failure to recognize the presence of lumbar abscesses. He related two very remarkable cases illustrating such oversight on the part of practitioners generally regarded as well posted in their profession.

Dr. Ransohoff thought that the same charge of incompetency could not be truthfully brought against the practitioners of Southern Ohio as Dr. Hamilton had made against those of Central Ohio. He emphasized the statement of Dr. Finger that lumbar abscesses are only symptoms, and holds that unless the cause can be removed free incision and drainage of lumbar abscess is bad treatment.

Dr. Geiger said his experience with these cases had been unfortunate. He considered it a matter of great importance that the after-treatment of these cases should be in the hands of competent surgeons.

Dr. Ross, of Pennsylvania, here related a case of erroneous diagnosis of purulent accumulation in the chest, which had no apparent connection with the subject under discussion.

Dr. Andrews, in closing the discussion, said there was no way of diagnosticating these cases in the very commencement. When the pus has formed to such a degree as to cause pressure there will be some elevation of temperature, and as soon as there is reasonable probability of the presence of pus it may be determined positively by the use of the aspirator. He does not favor the use of the knife until there is some physical evidence of the presence of pus. Incision is only a means to an end, rendering possible fuller exploration and the adoption of means of treatment which would be otherwise impracticable.

Dr. Byrd, of Illinois, then read a paper, prepared by his assistant, recounting a case of

INTRAVENOUS INJECTION OF SALINE SOLUTION

for collapse from hemorrhage, in which he injected eighty ounces of a saline solution into a vein of the arm.

The Section adjourned to meet at 2 P.M. Thursday.

Thursday, May 6th—Third Day.

Dr. R. Harvey Reed, of Mansfield, O., read a paper on

SOME COMPLICATIONS IN STRANGULATED HERNIA.

He reported a case in which a small obscure femoral hernia was complicated with hydrocele, an enlarged and adherent testicle, and a large, reducible, inguinal hernia, which was supposed to be the chief source of the difficulty. Another case was one operated upon by Dr. Senn, who had furnished him an account of the case. The omentum was adhered to the whole inner surface of the sac, and in operation it was necessary to remove the whole mass, and unite the edges of the ring; these were freshened and closely sutured. The result was complete cure. Another case was one in which a patient made unnecessary muscular operation while the wound was yet ununited, with the result of a new protrusion and a rupture of the protruding bowel. The parts were thoroughly cleansed, the rupture of the bowel was closely sutured, and the patient made a complete recovery.

Dr. Henry O. Marcy's paper was

A PLEA FOR RADICAL OPERATION FOR THE CURE OF HERNIA.

His operation consists in the ablation of the sac, freshening the pillars, and suturing them with chromicized kangaroo-tendon sutures. He thinks this operation far superior to those which have been advocated so zealously of late years by Dr. Warren, of Boston, and others, viz., by injection of an astringent liquid; this method he objects to, as being essentially blind surgery. He thinks operative interference of this nature is demanded wherever there is strangulation, where there is failure of the instrument (truss) to retain the hernia, and in cases of infantile hernia, which is with difficulty controlled by the truss, he has found the kangaroo-tendon sutures exceedingly valuable and satisfactory. He was the first to introduce this material to the profession.

In discussing these papers Dr. Hoadley reported an operation in which he had taken pains to ligate the freshened edges of the pillars as closely as possible; he was disposed to lay considerable stress upon the importance of this close suturing in order to secure perfection.

Dr. Quimby urged the importance of early operation. He thought operation should be performed within twelve hours after indications are apparent.

Dr. Smith, of Iowa, used to be very timid of removing omentum, but now has no hesitation in doing this when necessary.

At this point a committee of three, consisting of Drs. Gunn, of Chicago, Dawson, of Cincinnati, and Barton, of Philadelphia, were appointed to examine a case supposed to be of surgical interest. It proved to be the case of a young man, who, some months ago, was thrown upon the pommel of his saddle. Since that time he has been subject to pains in the abdomen, not so severe as to necessitate a discontinuance of labor, but at intervals of about a month enough to occasion severe suffering. His physician, in examining him recently, had discovered an adventitious growth at upper inner part of the thigh, which it was thought might have some relation to his pain. The committee, after examination, were agreed that the hard mass which had developed there was the result of an ossification of about two inches of the tendon of the adductor magnus muscle.

Dr. C. A. Todd, of St. Louis, then read a paper which gave the result of some careful studies in the dissecting-room, showing how the iliac arteries act as valves upon the venous flow into the inferior vena cava.

The paper was brief, and was passed without discussion.

Dr. Charles Fenger, of Chicago, then read a paper on osteoplastic resection of the foot, excision of the heel, as devised by Whadirniroff and Miculicz. Only a portion of the paper was read, and Dr. Fenger illustrated by a large drawing, by a plaster cast, and by the bones of a normal skeleton, the method of performing the operation as devised by the Russian and German surgeons independently, exsecting the calcaneum and astragalus, and removing the cartilaginous ends of the tibia and of the scaphoid and cuboid bones, and bringing the sawed surfaces together so that the patient can step upon the toes. He described a modification in the lateral incision by which he secures a fuller supply of blood for the nourishment of the foot than is gained by the operation as previously performed, making a decided improvement in it. The indications for the operation are: 1. Extensive injury to heel and adjacent parts of the foot; of the nineteen recorded cases, not one has been done to meet this indication. 2. Caries or tuberculosis of the os calcis and adjacent tissues; this is the most frequent cause noted. 3. Extensive disease of the soft parts of the heel. The after-treatment consists of keeping the foot at rest upon a splint, either of plaster or an interior and posterior.

Dr. MacLean spoke quite strongly in favor of Syme's operation, which he much preferred to the one described in the paper. He said he had made Syme's operation thirty-three or thirty-four times with generally very satisfactory results.

Dr. Quimby, of New Jersey, described an operation of his own devising, in which there is only a partial exsection of the os calcis, and no disturbance of the cartilage of the tibia, but the cut surface of the os calcis is

turned up into contact with the cartilage of the tibia. He has found the results to be satisfactory, and specially advantageous in the case of young children, as by this method the development and growth of the tibia is not interfered with.

Dr. J. M. Barton, of Pennsylvania, read the next paper, on the

VERTICAL EXTENSION IN THE TREATMENT OF FRACTURE OF THE FEMUR IN CHILDREN.

In five cases which he has treated by this plan most satisfactory results have been obtained, and the treatment was much simpler and easier than by other methods in common use. Bryant is credited with the first proposal of this treatment. The treatment is vertical instead of horizontal extension. One of the special advantages is the facility with which the patient can be kept clean.

Dr. Quimby, of New Jersey, did not see the advantage of the position, and strongly favored Buck's extension.

Dr. Link, of Indiana, was of the opinion that too much stress had been laid on extension and counter-extension. The three points which he gives as essential in the treatment of fractures are bandaging, flexion, and rotation. He bandages to control spasmodic action of muscles, flexes, and rotates outward in order to relax them. He had not used extension or counter-extension for years.

Dr. Belfield, of Chicago, read a paper advocating

DIGITAL EXPLORATION OF THE BLADDER,

including a report of ten cases of vesical tumor and enlarged prostate. He gave indications for this procedure, and contra-indications.

Dr. Robert Newman, of New York, then read a paper on

THE GALVANO-CAUTERY IN DISEASES OF THE PROSTATE, BLADDER, AND URETHRA,

exhibiting apparatus and demonstrating the mode of using the same. There was no discussion of these papers.

Dr. Glover, of Terra Haute, Ind., read a paper on the

TREATMENT OF ANAL FISTULA ASSOCIATED WITH PHTHISIS.

It was a collection of the opinions of a large number of physicians and surgeons in regard to the advisability of operating in such cases. The greater number seemed to favor operation, on the ground that it is best to relieve the patient of one disease, if possible, rather than allow him to be afflicted by both of them.

Dr. J. B. Johnson opposed this view, holding that the effect of arresting the drain by the fistula was calculated to intensify the morbid process in the lungs.

The Section adjourned.

SECTION ON OBSTETRICS.

TUESDAY, MAY 4TH—FIRST DAY—MORNING SESSION.

Dr. S. C. Gordon, of Portland, Me., President; Dr. J. F. Y. Paine, of Galveston, Tex., Secretary.

After a few remarks by the President, the first paper was read by Dr. W. H. Wathen, of Louisville, Ky., on the

TREATMENT OF THE MEMBRANES IN ABORTION AND LABOR.

One year ago he read a paper before this Section on the "Treatment of Secundines in Abortion and Labor." He divided his subject into three stages, premature labor, labor at term, and abortion prior to the sixth month. In abortion after the eighth week the membranes should be removed entire, if not expelled in twenty minutes. Should the woman show symptoms of syncope from hemorrhage, the shock of the removal of the membranes is not more than that of tamponing the vagina. Seventy-seven per cent. of cases of secondary hemorrhage occurred after the expectant plan, thirty-two per cent. after expression. Pajot reports out of sixty-eight cases of retained placenta that sixty resulted fatally. If the operation is done without delay the os is dilated or dilatable. The fingers are best to insert. Tents should be avoided; dilators may be used. If the patient is under an anæsthetic the entire hand may be passed into the womb. In premature labor and labor at term the placenta is easier separated.

The membranes can generally be removed by judicious expression, but if not, it is better to remove by force. He recommended Crede's method, and that the hand be always kept over the uterus. Crede removes the membranes in four and a half minutes, with universally good results. It was better, however, to give more time for coagula to form. If the membranes are held in the uterus by a cicatricial contraction, dilate this contraction to remove them. We should always have a hypodermic syringe charged with ergot to use if necessary. We should never use ergot until the membranes are expelled.

Dr. Fuller, of Maine, thought the paper a very practical one. The speaker's course had uniformly been to deliver the after-birth as soon and readily as he could. His experience had been that prompt removal of the placenta stops and prevents hemorrhage. He is generally careful to secure the placenta in five minutes after the birth of the child. He regards this promptness as a matter of safety.

Dr. W. P. King, of Sedalia, Mo., during the past twenty years had 719 natural labors and twice as many abortions. If near term, he practised the early removal of the placenta, generally waiting a long enough time for the appearance of one other pain. He said he unbuttoned the placenta with his fingers, and turned it out as a boy turned his tongue out of his mouth. He recommended dilatation with the finger and with the forceps, then to go in with the duck-billed forceps. He never failed during the last few years to wash out the uterus with a hot sublimate solution—115° to 135°, and a strength of 1 in 4,000. He carried a concentrated solution and made it on the spot. He used the reflex catheter, and washed until the water returned clear, having first rendered the hand aseptic. The two cases so often quoted, the Indian and the white woman, were not analogous cases. He strongly recommended asepsis and the clean removal of everything.

Dr. Garcelon, of Maine, asked if he understood the last speaker correctly that he had twice as many abortions as natural labors.

Dr. King replied that he did.

Dr. Garcelon then asked what sort of people he lived among

Dr. King said they were chiefly immigrants from New England.

Dr. C. R. Reed, of Middleport, O., said he did not wait so long now to deliver the placenta as formerly. He found the longer you waited the more firmly the os contracted and the greater the difficulty to remove the placenta.

Dr. W. W. Potter, of Buffalo, thought this would always form an interesting point of discussion. He criticised the manner in which the terms massage and Crede's method had been used in the discussion. Merely pressure suprapubic was not Crede's method, but to place the fingers behind and the thumb before the fundus uteri, and press out the placenta as you would a peach-stone. Beyond and above the question of hemorrhage is that of hyperplastic subinvolution.

Dr. Morris, of Baltimore, favored the opposition to delay. He never allowed a woman to lie twenty minutes without delivering the placenta. He believed in heroic treatment, though in abortion we cannot treat so heroically.

(To be continued.)

AMERICAN SURGICAL ASSOCIATION.

Seventh Annual Session, held at Washington, D. C., April 28, 29, 30 and May 1, 1886.

WEDNESDAY, APRIL 28TH—FIRST DAY—MORNING SESSION.

THE Seventh Annual Session of the American Surgical Association was held in the reading-room of the Army Medical Museum, Washington, D. C.

The meeting was called to order at eleven A.M. by the PRESIDENT, MOSES GUNN, M.D., of Chicago.

After the calling of the roll, the President delivered his

ANNUAL ADDRESS,

an abstract of which follows:

FELLOWS OF THE AMERICAN SURGICAL SOCIETY: Custom, if not organic law, requires the President to open the proceedings by a more or less formal address. I shall indulge in a few thoughts on certain points in the

PHYSIOLOGY AND SURGERY OF MOTOR, SENSORY, AND MOTO-SENSORY OR COMPOUND NERVES.

Previous to the investigations of Magendie and Bell, no clearly-defined effort had been made to differentiate the motor and sensory nerves. It remained for these investigators to clearly establish the fact of the motor qualities of the anterior roots and the sensory qualities of the posterior roots. With this also came the idea that this difference was intrinsic and due to peculiarities in the anatomical and physiological organization of the nerve-fibres. This appears to have been the idea generally entertained. Is this a fact? or is the difference to be found in extrinsic conditions, viz., the anatomical organization at either end of the nerve, the nerve-trunk being simply a conductor of a form of force. Upon the facts of the case depends the possibility of satisfactory results in the section and physiological reunion of divided compound nerves, and the grafting of one compound nerve upon another, where there has been so great a loss of the trunk as not to permit of the approximation of the distal and proximal portions of the nerve. Success in achieving satisfactory results by such operations or a uniform lack of success must afford a tolerably reliable answer to these interrogatories, much more reliable than experiments on some of the inferior animals.

EXPERIMENTS ON ANIMALS

require severe scrutiny, or they may mislead. Some of the experiments on animals were then referred to. Philipeau and Vulpain divided in dogs the pneumogastric and sub-lingual nerves and united the central end of the pneumogastric with the distal end of the sub-lingual. They also divided the lingual branch of the fifth nerve and the sub-lingual, uniting the central end of the lingual branch of the fifth nerve to the peripheral end of the sub-lingual, and tearing out the central end of the sub-lingual. The result of these experiments was, that after a time motion and sensation were restored. Other similar experiments were cited.

In April, 1880, Dr. E. P. Davis made for the speaker the following experimental operation: Under an anæsthetic the axillary plexus was exposed. The median was severed after its bifurcation, and also the ulnar and radial. The outer head of the median was united to the ulnar. The inner head of the median was united to the radial in the same way. At the end of ten days, the dressing was removed and complete paralysis of motion and of sensation found. In four weeks this began to disappear, and later a perfect condition of motion and sensation was observed. By this operation the distal portion of the median was left entirely without nervous supply, and yet there was no paralysis of muscles or integument supplied by this portion of the nerve. Later investigation shows that in the dog and certain other animals there is an anastomosis of fibres between different nerves, forming an indirect route for the conduction of nervous force.

Nerve-suture in man has become a recognized operation, both as a secondary and primary procedure. It must be concluded from experiments that

MOTOR, SENSORY, AND TROPHIC POWERS DO NOT DEPEND ON THE NERVE ITSELF,

nor on a difference of nerve-force, but on the organism at the end of the nerve. Professor Stephani is reported to have succeeded four times in uniting the distal end of the median with the proximal end of the musculo-spiral and the distal end of the latter with the proximal end of the former. Immediately following the operation were complete paralysis and atrophy, but in the course of six or eight months there was not only restoration of muscular power, but harmony of action to an extent sufficient to permit the animal to run, but perfect extending power was not realized.

THE INTERGRAFTING OF A SECTION OF A NERVE

of an inferior animal to replace extensive loss of nervous structure will probably be of too uncertain success to constitute a standard operation, but can the grafting of the distal end of a nerve in such a case upon the side of or into the trunk of an adjacent nerve secure to it a supply of nerve-force? Experiments made by Kawa would indicate that such might be the case. To establish this point experiments on dogs are valueless on account of the free anastomosis. We must look for the solution of this question to the rare opportunities met with in the course of surgical practice to institute experimental operations on man. A case has been reported by Després, where there was such extensive destruction of the median nerve as to preclude the possibility of approximating its ends. He therefore engrafted the distal end of the median with the trunk of the ulnar. Fifty-four days after the operation the functions of the parts supplied with the median nerve were partially restored.

The speaker had occasion recently to resect over three inches of the right ulnar nerve in the removal of a neuroma in a male patient aged thirty-six. The sheath of the median was removed, and the broadly chamfered end of the ulnar laid in contact with it and secured by three fine catgut sutures. Immediately after the operation there was complete paralysis of the parts supplied by the ulnar. On the eighteenth day there was a slight return of sensation along the ulnar side of the ring-finger, and there seemed to be some contraction of the flexor carpi ulnaris. Four months after operation, the patient could feel a slight touch on the ulnar side of the ring-finger, no sensation to touch in the little finger, but an increased warmth in it. He can now adduct the hand with considerable vigor, but as yet has no power over the terminal phalanges.

The positive evidence which these two cases furnish at so early a date warrants further effort in this direction, and corroborates the other evidence of the correctness of the postulate that the function of a given nerve depends entirely upon the machinery at its ends, and not upon any intrinsic quality.

The speaker concluded with a few words of welcome to the Fellows of the Society, expressing the hope that this meeting would be the occasion of renewing old friendships and forming new ones.

Upon the conclusion of the address, letters from distinguished Honorary Fellows were read, and a proposition to form a

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was discussed, and referred to a committee of three, to report Thursday morning, the committee consisting of Drs. J. Ewing Mears, Wm. T. Briggs, and Christopher Johnston.

AFTERNOON SESSION.

DR. CHRISTOPHER JOHNSTON, of Baltimore, read a paper entitled

DIAGNOSTITIAL LAPAROTOMY.

This operation, he said, is as ancient as our race, but in early times was always practised on the cadaver. The rapid advance of abdominal surgery now demands the attentive consideration of surgeons, and requires the expression of opinion as to the position of the line limiting interference in certain classes of cases. The labors of gynecologists and surgeons have greatly lowered the mortality of laparotomy for ovariotomy and hysterectomy, but the pathological possibilities of the male and female abdomen still constitute many difficult problems, which the knowledge and zeal of surgeons are constantly striving to solve. The question arises, How shall the seat of the pathological change be reached? The answer is laparotomy, which makes the diagnosis positive in cases of doubt, and is preliminary to other operations which may be required. If the surgeon has no right to refuse to give air to a fellow-creature becoming asphyxiated from obstruction in the air-passage, has he the option of refraining from surgical interference when the primæ viæ are obstructed in their functions? The propositions, then, are, first, that for abdominal surgical affections all possible operations ought to be attempted after the establishment of a precise diagnosis; and second, that when a just diagnosis cannot otherwise be reached, it may, and ought to be, determined by an exploratory incision. The mortality of abdominal incision without complication is low. It is unfair to compare dissimilar operations involving the peritoneum, for some have been so frequently performed that new methods and resources have been applied to them. A great consecutive mortality following a surgical procedure in nowise determines the want of value of the operation, while most cases recovering are to be considered a certain gain.

The abdominal incision intentionally diagnostitial is fraught with so little comparative ill consequence that its high value or necessity may be fairly claimed as an established and proper aid to diagnosis. Of all operations requiring laparotomy, those involving the uterus and its appendages probably fill the largest space. Next we have those involving the alimentary tract.

Speaking of the

CÆSAREAN SECTION,

the speaker said that comparing the mortality of this operation in former days with the mortality of the Porro-Muller operation, we find that while shock and other dangers are greatly increased in the modern operation, the mortality remains about the same. The old operation is, as a rule, done under objectionable surroundings, by inexpert operators, while the modern operation is done by experts, with the best surroundings. We have yet to see what the old operation will accomplish when the same safeguards are thrown around it that are given to the newer operation.

WHEN IS EXPLORATORY LAPAROTOMY CALLED FOR?

It should be stated that to a certain extent every laparotomy is diagnostitial. Without establishing unnecessary groups, two great classes in which exploratory laparotomy is demanded or permissible are to be recognized. First, all sorts of cases in which the diagnosis cannot be made without its aid. Second, all those cases in which a diagnosis having been made no definite line of operation can be mapped out, and no abandonment of active measures be entertained or justified. As in these cases laparotomy holds the key in all cases of doubt, both as to what is the matter, and what is to be done, it should be called upon to surrender that key. In intestinal cases the early operations are those which save life the oftenest, but abandonment ought not necessarily follow delay in invoking the surgeon's aid.

DR. A. VANDERVEER, of Albany, said there could be no doubt that experience shows us that simple incised wounds of the abdomen without injury to the abdominal organs will usually heal without difficulty, even if left to themselves. The mortality is very slight indeed. Even when the injury is more serious, recovery often follows. The cases which give us anxiety are those in which the bowel is injured and its contents escape into the abdominal cavity. These die inevitably if nothing is done. In these cases laparotomy should be performed. This view is often opposed by the friends of the patient, and also by the attending physician. Much will have to be done in the direction of teaching the profession and the public the importance of early operation in these cases. Cases were cited of gunshot injuries of the intestine, and of rupture of the intestine produced by external violence, in which the operation might have saved life if it had been permitted by the friends of the patient. The operation, as a rule, will not be permitted until the patient is in collapse, and it is then too late. Dr. Johnston had presented points of great interest and importance. This operation should be done more frequently in the future than in the past. As regards the mode of operation, the incision in the median line is by far the best. In some cases it would be impossible to reach the seat of disease by any other incision. In the closing of the wound some recommend several lines of sutures, uniting the different layers of tissue separately. He considered this no advance on the old method of using sutures including all the layers of tissue. Where there is great distention of the bowel in intussusception the discovery of the seat of trouble is greatly facilitated by a procedure which he had seen Tait adopt in such a case. He opened the distended coil of intestine, permitted the gas to escape, and then closed the opening with sutures.

DR. J. EWING MEARS, of Philadelphia, said that in considering diagnostitial laparotomy he would arrange the subject in this manner. In the first place, we should use external manipulation; second, internal examination where this is possible; third, aspiration, and finally, laparotomy. He regarded laparotomy as much the most serious of all these methods. The more experience he gained the greater was his conviction that

THE ABDOMINAL CAVITY SHOULD NOT BE OPENED WITHOUT DUE CONSIDERATION.

Death is a severe penalty to pay for the perfection of the diagnosis. We have already learned a great deal in regard to methods of diagnosis by external manipulation, but the tendency at the present time seems to be in favor of opening the abdominal cavity rather than cultivating that essential skill by which the diagnosis may often be made without resorting to operation. . . . Tait's assertions, that opening of the abdominal cavity is a matter of very little consequence, has led many of the younger members of the profession to perform this operation without due consideration. I agree with Dr. Johnston that having exhausted other methods of diagnosis, if the patient's life depend upon it, we should open the abdomen. He believed that in intestinal obstruction the abdomen should be opened, and that many lives have been lost by want of courage on the part of the surgeon. There is no question as to the duty of the surgeon in the case of gunshot wounds of the intestines.

DR. CHARLES T. PARKES, of Chicago, thought that the size of the incision made very little difference so far as the final recovery is concerned, but when the incision extends above the umbilicus recovery is slower and attended with more inconvenience. In the cases which he had seen where post-mortem examination followed, there was no evidence that the abdominal incision had anything to do with the fatal issue. He related the case of a child, eighteen months of age, in which the operation was declined, and in which, at the post-mortem, intussusception

of the small intestine was found, which was without adhesions and could readily have been removed.

The abdominal opening should be made in the median line. In regard to closure of the wound, he thought that the simple suture going through all the tissues had been followed by such good results that we need use no other. Where there is much distention of the intestine, the method by opening the bowel is the best. When the exploratory needle is used, it is necessary to make a number of punctures. In two instances he had found extravasation of fecal matter through these punctures.

Dr. McLane Tiffany, of Baltimore, had lately seen four cases of intestinal obstruction. In all four laparotomy was proposed. Two refused, and both of these died. Two accepted, and one of these recovered. The case that died was that of a woman, aged seventy-three, in whom the obstruction had lasted seven days. The intestine was enormously distended, and in the examination ruptured with the escape of the gas. After this it was extremely easy to find the seat of constriction. The shock would be lessened if the intestine were emptied. He agreed with the speaker as to the great value of laparotomy as a diagnostic operation, and he said it was not possible for any human being to recognize through the abdominal walls the manifold conditions of the organs present.

Dr. J. F. Thompson, of Washington, reported

TWO CASES OF LAPAROTOMY

for the purpose of diagnosis. A woman, aged thirty-five, had the history of an abdominal tumor lasting for several years. It presented the appearances of an ordinary ovarian tumor, with the exception that it had two sinuses communicating externally. After frequent examinations by various surgeons, it was decided to make an exploratory operation. One of the sinuses was traced back to the peritoneum, without reaching any satisfactory explanation of the tumor. The peritoneum was then opened, and the finger introduced, but no tumor in the cavity could be felt. Toward the abdominal wall a mass could be distinguished apparently imbedded in the tissues. The wound was closed and the patient recovered from the operation, but she subsequently died from other causes, and the post-mortem showed that the tumor was an enlarged spleen which had fallen down below the umbilicus, and become attached to the abdominal wall.

The second case was one of carcinoma, involving the transverse colon which ran directly through the mass. There was also an attachment of the growth to the liver. The abdomen was closed, the patient recovered from the operation, and is still living.

The author of the paper, in closing the discussion, said that there was a certain hesitancy on the part of surgeons in regard to operating in cases of abdominal injury, on account of the people and on account of juries. To overcome these objections it would be necessary to educate the public to the true state of affairs. He was glad to find his opinions supported by so many of the able minds of the profession.

Thursday—Second Day—Morning Session.

Harold C. Ernst, M.D., of Jamaica Plains, Mass., read a paper entitled

A CONSIDERATION OF THE BACTERIA OF SURGICAL DISEASES.

After an extended description of the various bacteria met with in wounds, chronic abscesses, erysipelas, and other surgical affections, and an account of numerous experiments on animals, with an exhibition of specimens in culture mediums and under the microscope, the author presented the following conclusions: I. The experiments conducted over so long a time, with the successful inoculation at the end of that time, indicate very plainly the retention of pathogenic powers of these organisms indefinitely. II. Their permanence of form is also well established. III. In order to obtain either a modification of their pathognomonic forms or of their morphological properties, if this is possible at all, some different methods of investigation must be used than those which have hitherto been employed. IV. The probabilities indicate that work in this direction is not likely to be successful. V. So far as the experiments go, they tend to show that no form of the suppurative process in man is unattended by bacteria, and that the inoculation in the lower animals of pure cultures of these bacteria is followed by more or less acute and extensive suppuration. VI. The above conclusion is supported by the evidence of all workers in this field of research. VII. A number of different clinical phenomena may be produced by the same organism, all of these phenomena, however, coming under the general head of the inflammatory and suppurative processes. VIII. The difference in the results produced by the same micro-organism in different individuals depends upon influences outside of the bacteria themselves. IX. These differences are the result of differences in the amount of the infectious material received into the system, and of the locality or lesions by which it gains access, and also by variations in the individual condition—the personal equation being a very large factor in making up the sum of any results in bacteriological work.

Dr. S. W. Gross, of Philadelphia, said that the observations made by Dr. Ernst confirm those made by other observers, showing very conclusively that the suppurative processes are dependent upon vegetable organisms. The most interesting part of the paper was that which relates to chronic suppuration. Dr. Ernst had been the first, he thought, to show that chronic suppuration is due to the same micrococci as the acute form.

Dr. J. S. Billings referred to the difficulties encountered in this work. It is only by personal experience that they are learned. One of the difficulties in considering the probable relation between cause and effect is that there seems to be no relation between the number of micrococci present and the effects produced. A second difficulty is that we are by no means sure of the specific differences between these various forms of microscopical organisms.

Dr. N. Senn, of Milwaukee, desired to say a few words in regard to the conditions which predispose to the action of germs introduced into the body. The object of the surgeon should be, in the first place, to prevent the introduction of these germs, and, in the second place, to secure inocuity to the infection by preventing the occurrence of predisposing causes. The first predisposing condition is found in an unusual arrangement of the capillary circulation. This is well illustrated in

OSTEO-MYELITIS.

In this affection the germs are found in greatest abundance in those situations where the anatomical relations of the vessels predispose to engorgement and localization of the microbes. This is in the large vessels about the centres of ossification in the epiphyses of bones. The second predisposing influence is traumatism. The germs of osteo-myelitis may be present in the body for a long time, and produce no effects until the occurrence of traumatism, as a fracture favors the localization of the microbes.

Dr. David Prince, of Jacksonville, Ill., exhibited a diagram and described a form of room whereby

A STERILIZED ATMOSPHERE

could be secured for the patient by means of air treated with corrosive sublimate, and forced through a tube opening immediately above the seat of operation.

THE REPORT OF THE COMMITTEE

on the organization of a congress of American physicians and surgeons was then presented.

In view of the fact that there are many special medical organizations now in existence in the United States, and also that many representative men in the medical profession are members of two or more of these associations, the committee thought it would be advisable to make arrangements with these societies whereby uniformity as to the time and place of their several meetings might be obtained. In this way their members might be spared the expense and loss of time entailed upon them when obliged to make several distinct trips to different places each year.

The plan proposed was to unite the following-named associations into a congress to be called

A CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS:

The American Surgical Association, the American Ophthalmological Association, American Otological Association, American Neurological Association, American Laryngological Association, American Gynæcological Association, American Dermatological Association, American Climatological Association, and the American Clinical and Pathological Association.

THE PLAN OF ORGANIZATION

embodies the following: Each society is to elect its own officers; hold its own sessions apart from the others at the time and place of meeting; publish its own transactions; and do all other acts which by virtue of its constitution and by-laws it has the inherent right to do, thus preserving its own autonomy.

It was proposed that the congress be composed of these special societies when in convention, and that its meetings be held in the city of Washington; the constitution and by-laws of the congress to be formed by a committee of equal number from each special society. The opening session of each annual meeting of the congress to be devoted to such general business as may pertain to the interests of the association as a whole. The congress being presided over by a president elected annually, and who must deliver an opening address on the first day of the session. The president to be chosen by a nominating committee of one from each special society; the presidents of the special societies to be *ex-officio* vice-presidents of the congress. Membership in the congress to be acquired only by virtue of fellowship in one or another of the special organizations. The other officers to be elected as determined upon by the convention in session.

The committee disclaimed any intention of opposing any other organization in America, but proposed simply a plan of uniting into one great body the already existing special societies, doing so from an honest conviction that such a union will prove of inestimable benefit to them individually and collectively.

The committee appointed to consider this proposition reported that they viewed with great satisfaction the perfection of a plan through which the meeting of the above-named societies at the same time in Washington may be accomplished, and recommended the adoption of a resolution that a committee of five be appointed to confer with committees from other special organizations to arrange details and to report at the next annual meeting of the association. This was adopted.

The session then adjourned.

AFTERNOON SESSION.

The first paper was by DR. N. SENN, of Milwaukee, and was entitled

THE SURGERY OF THE PANCREAS AS BASED UPON EXPERIMENTS AND CLINICAL RESEARCHES.

The following conclusions were presented: 1. Restoration of the continuity of the pancreatic duct does not take place after complete section of the pancreas. 2. Complete extirpation of the pancreas is invariably followed by death, produced either by the traumatism or gangrene of the duodenum. 3. Partial excision of the pancreas for injury or disease is a feasible and justifiable surgical procedure. 4. Complete obstruction of the pancreatic duct, uncomplicated by pathological conditions of the parenchyma of the organ, never results in the formation of a cyst. 5. In simple obstruction of the pancreatic duct the pancreatic juice is removed by absorption. 6. Gradual atrophy of the pancreas from nutritive or degenerative changes of the secreting structures is not incompatible with health. 7. Physiological detachment of any portion of the pancreas is invariably followed by progressive degeneration of the glandular tissue. 8. Extravasation of pancreatic juice into the peritoneal cavity does not produce peritonitis. 9. Crushed or lacerated pancreatic tissue is removed by absorption, provided the site of operation remains aseptic. 10. Complete division of the pancreas by elastic constriction is never followed by restoration of interrupted anatomical continuities. 11. Limited detachment of the mesentery from the duodenum, as required in operations upon the pancreas, is not followed by gangrene of the bowel. 12. In all operations upon the head of the pancreas the physiological attachment of the peripheral portion of the gland should be maintained by preserving the integrity of the main pancreatic duct. 13. Partial excision of the splenic portion of the pancreas is indicated, in cases of circumscribed abscess and malignant tumors, in all cases where the pathological product can be removed completely without danger of compromising pancreatic digestion or of inflicting additional injury upon important adjacent organs. 14. Ligation of the pancreas at the point or points of section should precede extirpation as a prophylactic measure against troublesome hemorrhage and the extravasation of pancreatic juice into the peritoneal cavity. 15. The formation of an external pancreatic fistula by abdominal section is indicated in the treatment of cysts, abscess, gangrene, and hemorrhage of the pancreas due to local causes. 16. Abdominal section and lumbar drainage is indicated in cases of abscess or gangrene of the pancreas in which it is found impossible to establish an anterior abdominal fistula. 17. Thorough drainage is indicated in cases of abscess and gangrene of the pancreas, with diffuse burrowing of pus in the retro-peritoneal space. 18. Removal of an impacted pancreatic calculus in the duodenal extremity of the duct of Wirsung by taxis, or incision and extraction, should be practised in all cases where the common bile-duct is compressed or obstructed by the calculus, and death is threatened by cholæmia. 19. In such cases the principal source of danger, extravasation of bile into the peritoneal cavity, should be avoided by preliminary aspiration of the dilated bile-ducts, accurate closure of the visceral wound with fine silk sutures, and absolute physiological rest of the organs of digestion during the time required in the healing of the visceral wound.

Remarks in discussion were made by Drs. Conner, Fenger, and Parks.

DR. CHAS. T. PARKS, of Chicago, read a paper, supplemental to his paper of last year, reporting

TWO CASES OF CHOLECYSTOTOMY,

both of which ended fatally. In discussing the paper,

DR. W. H. CARMALT, of New Haven, described the following case: The patient, a woman, thirty-seven years of age, had suffered for several years with indefinite dragging sensations in the right hypochondriac region. This incapacitated her from performing her household duties. In 1883 she stated that she had been operated on in Berlin for floating kidney, and in evidence showed a large scar in the lumbar region. She also stated that three weeks after operation, as a result of violent sneezing, the organ had become loosened. She came to the speaker for the purpose of having the kidney removed. Examination showed the abdomen to be exceedingly pendulous. The tumor was rounded and could be readily grasped between the fingers. It was very movable. An incision

was made, and it was at once evident that it was not the kidney. Further examination showed it to be a dilated gall-bladder. An aspirator was introduced, and four ounces of inspissated mucus drawn off. Five calculi were found. The gall-bladder was closed with a continuous catgut suture. The wound in the peritoneum was closed in the same way. The muscles were united by interrupted silk sutures, and a continuous catgut suture was used for the incision in the skin. The patient made a good recovery, and is now able to attend to her duties.

In the absence of the author, DR. JOHN S. COLEMAN, of Augusta, the Secretary read his paper, entitled

A CASE SIMULATING ABDOMINAL PREGNANCY—LAPAROTOMY, CÆSAREAN SECTION, AND REMOVAL OF A LIVING CHILD.

February 27, 1886, the writer was requested to see B. A——, colored, primipara, aged twenty-four. The attending physician believed her to be the subject of extra-uterine pregnancy. She thought herself at the end of gestation, and for three days had suffered with pains which were quieted by the administration of laudanum. The entire abdomen was greatly distended, particularly in the upper portion. Vaginal examination showed procidentia, the os projecting three inches beyond the labia. The os was sufficiently patulous to permit the entrance of the index-finger. Rectal examination gave negative results. Palpation and auscultation showed the position of the fœtus to be dorso-anterior and obliquely transverse. Placental souffle could not be heard. The abdomen was so large, and the fœtal heart-sounds so distinct, that the writer also concluded that the case was one of extra-uterine pregnancy, and the patient was examined by a number of surgeons, who agreed in the diagnosis. The history and the symptoms indicated that the patient was at the full term of pregnancy, and it was decided that immediate surgical interference was imperative. An incision six inches in length was made in the linea alba. The exposed tumor much resembled the pregnant uterus. The incision was extended above the umbilicus, and it was positively determined that the case was one of uterine pregnancy. The uterus was drawn forward, and its anterior wall cut through. The writer had not conceived it possible for the uterine tissue to be prolonged from the epigastrium to three inches beyond the vaginal notch. A vigorous female child, weighing seven or eight pounds, was removed. The hemorrhage was not great. The placenta was removed without difficulty. The incision in the uterus was closed with deep and superficial catgut sutures. The peritoneum was closed with a continuous suture, and the abdominal wall with harelip-pins and superficial sutures. Antiseptic precautions were adopted throughout the operation, but septicæmia developed, the patient living but four days.

At the autopsy there was found no decided injection of the peritoneum. Two moderate-sized clots were found on the peritoneum, the cavity containing nearly a quart of bloody serum. The uterus was one-half its former size, measuring from fundus to os externum twelve inches. The cervix measured six inches. The wound was found gaping throughout.

The author then gave an extended review of the literature of the subject, and related similar cases by various operators.

To the paper was appended

A LETTER FROM MR. LAWSON TAIT,

indorsing the performance of abdominal section in the above case, and asserting his strong objections to operations looking to the breaking up of the fœtus. He thought that a preferable operation in the present case would have been the Porro operation. This would probably have been successful as regards both the mother and the child.

Adjourned.

THIRD DAY—MORNING SESSION.

DR. T. F. PREWITT, of St. Louis, read the first paper, which was entitled

TRAUMATIC ANEURISM OF THE INTERNAL CAROTID ARTERY.

The speaker first referred to those cases of spontaneous aneurism of the internal carotid artery which are found in literature, and the frequency with which this lesion had been confounded with cynanche tonsillaris. He had been unable to find more than one reported case of traumatic aneurism of this artery. This was reported by Dr. William T. Briggs, of Nashville. The aneurism in that case followed a stab wound, and was operated on successfully.

Dr. Prewitt then described the following case: E. J——, colored, seventeen years of age, was shot by her husband early in January, 1885. The weapon used was a revolver carrying a No. 32 ball. The shot was fired at a distance of two feet, and entered the cheek over the malar bone, ranging backward. There was profuse hemorrhage at the wound of entrance; there was no wound of exit; the bleeding was controlled by compression. There was hemorrhage from the ear at the time, and this recurred on two or three occasions. For some time after the accident the patient stated that there was some hemorrhage from the mouth and nose on rising in the morning. There was some swelling at the time, which gradually increased until April 2d, when she was seen by the speaker. It then projected into the pharyngeal cavity and rested against the uvula, and extended externally from the anterior petrous portion of the temporal bone to the hyoid bone. The swelling pulsated in every direction, and gave thrill and bruit. Immediately after the accident there was paralysis of taste and of the right side of the tongue; this continued. Pressure upon the carotid artery arrested the pulsation in the tumor. There was no difference in the pulsation of the two temporal arteries; the pupils were equal and responded normally to light. There was persistent headache, with sounds in the ear, which were increased by lying upon that side. The voice was greatly interfered with, owing to paralysis of the right vocal cord. The appetite was poor and the patient emaciated; she was unable to swallow solids, and fluids regurgitated when the attempt to swallow was made.

With this history and with these symptoms it was decided that there was an aneurism of the internal carotid artery, and that the vessel had been wounded near the carotid foramen, for nowhere else are the artery and nerve in such intimate connection.

It was determined to at once ligate the common carotid artery. The usual incision was made, and the dissection continued until the artery was exposed. A silk ligature was passed from behind forward. The vessel was then lifted, to be sure that the pulsation was arrested before the ligature was applied. Finding that it was, the vessel was then tied. The pulsation was at first arrested, but in a few minutes it could be again felt. In the absence of all precedent it was concluded to extend the incision upward in front of the tragus, and determine the feasibility of opening the sac and tying the distal end. This was a forlorn hope, for the diagnosis was that the aneurism was seated just external to the carotid foramen. An incision was then made below the ear, and extended upward back of the ear. A cautious dissection revealed the fact that the sac filled all the space between the mastoid process behind and the condyles and ramus of the jaw in front. It extended to the base of the skull, to which it was closely adherent. It was, therefore, impossible to reach the artery in that direction. Further attempts were abandoned, the wound was closed, a drainage-tube inserted, and an antiseptic dressing applied. On the eighth day there was some hemorrhage from an opening near the angle of the jaw. This was repeated, and she spat up some blood on the following

day. Examination showed a little coagulum at the angle of the jaw, which was removed, and the left forefinger thrust into the opening. No coagulum could be felt within the sac. The attempt to detect the entrance of the artery with the finger failed. In order to avoid the hemorrhage which would follow the removal of the finger, the sac was stuffed with lint treated with iodoform. This controlled the bleeding. The patient gradually became weaker, and died on the twenty-fifth day after operation, from exhaustion. Ten days after the sac was stuffed epileptiform convulsions, involving the facial muscles and the flexors of the forearm and hand, appeared. These continued at intervals until her death.

The post-mortem showed the ball in the posterior part of the sac. The opening of the carotid artery was found close to the carotid foramen, and seemed blocked up with clot. The blood-vessels of the membranes of the brain were congested, particularly on the right side. The inferior petrosal and lateral sinuses were filled with thrombi up to the torcular herophili.

DISCUSSION.

Dr. William T. Briggs, of Nashville, remarked that the case which he had reported at a previous meeting of the Association was that of a young man stabbed in the neck. Five weeks later the patient presented himself at the clinic with a swelling of the neck giving all the signs of a small aneurism of one of the branches of the external carotid artery that could be readily reached and ligated. An opening large enough to permit the introduction of the finger was made, and at once it was found that the condition was more serious. The hemorrhage was controlled by stuffing a sponge into the sac, and the common carotid ligated. When the sponge was removed, the hemorrhage was as free as before. The opening in the sac was then enlarged, the opening of the artery having been found and controlled by the finger. The vessel was then hooked up, and a ligature applied above and below the sac. The patient recovered, and is still living in perfect health.

Dr. D. Hayes Agnew, of Philadelphia, described the following case: About three years ago a woman presented herself at the University Hospital, with a tumor as large as an orange just beneath and behind the angle of the jaw. There was also a projection into the pharynx. This tumor had grown slowly for eight months, and was attributed to a blow on the side of the head. It was considered a case of aneurism of the internal carotid, and the speaker ligated the common carotid above the omo-hyoid muscle. The pulsation was diminished, but it could still be felt. He then tied the superior thyroid and the lingual; this stopped all pulsation. The patient did well for two weeks, when pulsation again returned. Pressure on the carotid of the other side controlled the pulsation, and he then placed a ligature around the primitive carotid of that side. During his absence from the city ulceration took place, and a gush of blood into the pharynx occurred. The resident stuffed the cavity, but the patient died eight days later, apparently from septic poison. In case rupture occurred, Dr. Agnew had determined to lay the sac open and have tied above and below. From the history of the cases he believes that in this condition the operation should be a formal one of section of the jaw and ligature above and below the sac.

Dr. A. Vanderveer, of Albany, reported the following: In December, 1882, a man, forty-two years of age, a farmer, was sent to him with a swelling of the neck, which was diagnosed to be an aneurism of the internal carotid artery. It was attributed by him to forced motion of the head to one side which was required in a certain part of his work. It was decided to first try compression. This was faithfully carried out, and at the end of six days the swelling was much diminished, and the tumor in the pharynx seemed more solid. He then went to his home, but returned one month later, the previous condition having returned. Compression was again tried, and at the end of five days there was a marked diminution in the the size of the tumor. He again returned home and continued in apparently good health for four or five weeks, when he suddenly complained of a severe pain in his head and fell dead. An autopsy was made, but no satisfactory explanation of his death could be found. The physician was inclined to attribute it to apoplexy.

Dr. L. McLane Tiffany, of Baltimore, said that in the case reported there was no room for a distal ligature. It might, however, have been possible to apply a compress, pressing the artery against the base of the skull. A record of such a case is found in Guthrie's "Commentaries." It is the case of Twitchel, of New Hampshire. A man had part of his neck blown away by a cannon-shot, exposing the carotid artery. Ten days later, while the physician was in the house, the artery gave way. The hemorrhage was controlled by the finger, and a ligature applied below the opening. The hemorrhage continued when the finger was removed. There was not room for a ligature on the distal portion of the vessel. The doctor made a graduated compress and pressed the artery against the base of the skull. The patient recovered.

Dr. T. F. Prewitt, of St. Louis, agreed with those who had taken part in the discussion, that the old operation is the proper one for traumatic aneurism where it is possible to apply it. In this case this could not be done. Compression had been alluded to, but we should not expect compression to succeed in a case where ligation failed. If the circumstances had been suitable, he would have tried compression, but the symptoms were too urgent to permit of this.

The next paper, by Dr. Roswell Park, of Buffalo, was entitled

LIPOMA TESTIS, OR A LARGE ACCUMULATION OF FAT IN THE TUNICA VAGINALIS.

J. P——, aged forty, was first seen in September, 1885. For eighteen months the patient had noticed a slow but continuous enlargement of the right testicle. This was almost painless, but caused inconvenience by its weight. At this time the tumor had reached the size of a cocoanut.

Examination showed the scrotum to be filled with a large mass, the testicles being crowded into a small pace at its upper part. This mass was solid, yet soft and not tender. Obscure fluctuation was noticed, but no fluid was obtained upon explorative puncture. The patient's general appearance excluded all idea of malignancy. The scrotal integument moved with perfect freedom over the tumor.

On October 4th the patient was operated on. A free incision through the tunica vaginalis revealed a mass of densely packed fat, which was slightly adherent but was turned out without difficulty. On separating the lobular masses by the fingers, the right testicle was found incorporated with the mass by apparently intimate tissue-connection. Finding the fibrous trabecula and blood-vessels radiating from the testicle to the fatty mass so numerous and distinct, it was decided to remove the whole en masse, which was done. The patient recovered without incident. After removal the mass weighed three pounds.

Dr. Park also read a paper entitled

NEPHRECTOMY ON A PATIENT TWENTY-THREE MONTHS OLD.

B. B——, born October 4, 1883, appeared at birth to be perfectly healthy. During the following winter the nurse noticed an enlargement in the right side of the abdomen.

July 31, 1885, the attention of the writer was called to the child, who appeared to be perfectly healthy. There was a history of steady enlargement of the growth. Examination of the abdomen revealed a firm, resisting tumor, about the size and shape of the fœtal head at term, occupying the right half of the abdominal cavity. A portion

of the fluid was removed and examined with negative results. The diagnosis was fibro-cystic tumor of the right kidney, probably of congenital origin. Five weeks later the tumor was found to have increased decidedly in size, and operation was decided upon.

The operation was performed September 15, 1885. An incision was made in the right semilunaris. Slight adhesions were found. The peritoneum covering the growth was incised, and the tumor shelled out without much difficulty. The pedicle was tied and dropped into the abdominal cavity. On the twelfth day the patient was removed to his home, and now, seven months after operation, is perfectly well. The tumor proved to be a fibro-cystic tumor of the right kidney, the cystic element predominating. Immediately after removal it weighed four pounds.

The case reported appears to be the youngest who has survived nephrectomy, he being twenty-three months old at the time of operation. The abdominal incision in this case was made not from choice, but from necessity, the tumor being altogether too large for extraction through a small opening in the lumbar region.

Dr. W. W. Keen, of Philadelphia, then read a paper on

STRETCHING OF THE FACIAL NERVE.

He first related a recent case in which he had done the operation, and added a table of the twenty-one cases so far reported.

His own case was that of a woman forty-eight years of age. She had had severe attacks of nervous trouble in early childhood, and had twice been paralyzed. Five years ago, coincident with menstrual disturbances, her right eyelids began to twitch, and in six months the whole face and the platysma were incessantly in spasm, which was increased by mental or muscular effort, such as eating, speaking, or being spoken to. Later, this was accompanied with constant pain.

In June, 1884, the right infra-orbital had been resected, with partial relief for only six weeks. Not long after the twitching extended to the right side and leg.

April 2d, Dr. Keen cut down on the seventh nerve by an incision behind the right ear, displacing the parotid gland forward and getting access to the nerve just after its exit from the stylo-mastoid foramen. Imbedded in connective tissue, it required considerable search and dissection to lay bare the nerve in this case. The exact point of its entrance into the parotid was quickly discovered by a very weak current of electricity, one electrode being placed on the cheek and the other, consisting simply of the wire, being touched at successive points from above downward. The trunk was then laid bare and stretched, the force being estimated at four or five pounds, just short of lifting the entire head.

Total facial palsy followed, with relief not only from the spasms in the face and neck, but also of that in the side and leg. The wound healed in four days, when the sutures were removed, the highest temperature having been 100.4°. The operation was done twenty-five days ago, and so far there has been no return of the spasms.

Next a table of the other twenty cases so far reported since Baum in 1878 first stretched the facial nerve was given, with remarks upon the operation.

The speaker preferred Baum's method of operating decidedly to Heuter's, in which the nerve is reached through the parotid gland. He bandages the lower jaw and gives fluid food for three or four days in order to keep the parts quiet while healing.

He called attention to two cases in which a palsy existing prior to the operation was benefited by the nerve-stretching, both electrical and voluntary control being obtained to some extent, and he suggested that in persistent facial palsy stretching of the facial nerve be tried as a therapeutic operation.

The discussion of Dr. Keen's paper was postponed to the afternoon session.

Adjourned.

(To be continued.)

THE FIFTH GERMAN CONGRESS FOR INTERNAL MEDICINE.

Held at Wiesbaden, April 14, 15, 16, and 17, 1886.

PROFESSOR LEYDEN, PRESIDENT, IN THE CHAIR.

WEDNESDAY, APRIL 14TH—FIRST DAY.

THERE was a full attendance at the opening of the Congress of the regular members, of which there are about two hundred, and there were also delegations of physicians from Switzerland and Holland.

The PRESIDENT, in his

OPENING ADDRESS,

said that while fully recognizing the great services rendered to medicine by recent discoveries in the exact natural sciences, it was important to remember that our art—applied medicine—must be practical, dependent mainly upon observation, and inseparable from the experience of former times.

PROFESSOR FRAENTZEL, of Berlin, then read the first paper, entitled

THE OPERATIVE TREATMENT OF PLEURITIC EXUDATIONS.

After a few general considerations, the author divided his subject according to the nature of the different exudations, giving the indications for operation and the mode of procedure in each case.

SERO-FIBRINOUS EXUDATIONS.

The indications for operative interference first given by Trousseau hold good to-day. Traube did much to propagate Trousseau's views in Germany, but it was through Bowditch's discovery of the possibility of uncovering the fluid by aspiration that the operation lost all the dangers that formerly surrounded it. Since 1871, the speaker had removed sero-fibrinous exudations by aspirations in more than four hundred cases, and without a single death attributable to the operation. He used a very small trocar and canula, made on the principle of Emmet's instrument for evacuating cysts, aspirates slowly, and withdraws no more than 1,500 c.c. in the course of half an hour at one sitting. He believed that in this way too sudden re-expansion of the compressed lung, with the symptoms of severe coughing fits, collapse, etc., are almost always avoided. The patient being always in the recumbent position (to avoid fainting), with shoulders slightly elevated, he drives his instrument with a rapid push through the fifth intercostal space on the left, through the fourth on the right side, between the mammillary and axillary lines, never posteriorly to axillary line unless it be for sacculated empyema prior to incision. The vital indications for operation are immense accumulation, suddenly disturbed or impeded circulation, threatening œdema in the lung of the sound side, and symptoms of collapse. In the general run of cases, the author considered it time to operate when the fluid reaches up to the third rib. Unless there be some vital indication, he waits until all fever has left the patient, and aspirates at the end of the second week in children, of the third week in grown persons. He never hesitates to repeat the operation as often as may be required in intervals of three or five or seven days.

HEMORRHAGIC EXUDATIONS.

Where the fluid contains but a slight admixture of blood, he does not hesitate to evacuate the chest, but real sanguinolent exudations should not be operated upon.

EMPYEMA.

In this condition the speaker advised the radical operation by one-inch or two-inch incision, with or without subperiosteal resection of a piece of rib in the same intercostal spaces as above. There should be thorough evacuation and cleansing of the cavity, to be continued until the warm water returns pure; then the

cavity should be washed with a weak antiseptic solution, and well drained, and the wound covered with an antiseptic dressing. The cavity must be thoroughly washed out again whenever the thermometer shows any rise of temperature; when suppuration continues, a broad rather flat silver or hard-rubber canula, without side plate, is introduced, and left as long as may be necessary.

PYO-PNEUMO-THORAX,

when of traumatic origin, is treated by the radical operation, when it is certain that the pleuritic exudation existed prior to the development of gas in the thorax.

PNEUMO-THORAX.

In the non-traumatic form of this affection, when a vital indication demands it, a puncture may be made, but great care must be taken to avoid the ingress of air. The author had seen several cases of pneumo-thorax in which the exudation has remained serous for three months.

With regard to the occurrence of rapidly developing and very large pleuritic exudations, he found that they mostly occur in individuals that are either phthisical or will soon become so—an experience in which all the members who took part in the discussion seemed to agree.

In the ensuing discussion, H. WEBER, of Halle, and FRIEDLER, of Dresden, were agreed that it is unnecessary to wait for aspiration until the patient is free of fever. They had operated in many cases in the second week, and even earlier, and repeated the operation as often as they saw fit, without apparent detriment to their patients. They also evacuated the fluid more rapidly than Fræntzel did, and do not hesitate to remove all, or nearly all, of it a tone sitting. They did not employ a trocar, but a sharp, good-sized aspirator-needle, in which a canula, with large eye on the side of the distal end, can be moved forward to and beyond the cutting point of the needle. To the proximal end of the instrument a tube, consisting partly of glass, partly of rubber, and from two to three inches in length, is attached. The tube, being filled with carbolized solution, is attached to the needle-apparatus, then dipped into a vessel at the bedside also filled with antiseptic liquid. The tube acts as a lever, and by depressing one end of it more or less down into the receiving-vessel, the exudation is withdrawn with varying rapidity and great ease, and no air can possibly enter into the thoracic cavity. The speakers preferred this apparatus to the aspirators generally in use, and have found it to facilitate the operation, making it perfectly safe at the same time.

DR. LITTUC proposed to resect, in the operation for empyema, a piece of the lower margin of one and the upper of the other rib, creating thereby an osseous channel which cannot contract, and would therefore have many obvious advantages. He said he had been pleased with this procedure, but others who have tried it found that they cut the intercostal artery in taking a piece off the lower part of the rib, and had great trouble in securing the bleeding vessel. Should the intercostal artery be injured after taking away an entire piece of a rib, there would be no difficulty in tying the vessel.

PROFESSOR JÜRGENSEN rose to say that for diagnostic purposes he as well as others had often thrust a hypodermic needle into the lung-tissue, and that it was never followed by any bad consequences. As to thoracic fistula in empyema, he had seen a number of cases that led him to believe that there was in consequence of this particular kind of chronic suppuration a great disposition to the development of amyloid degeneration.

A POOR JOKE.—Some would-be wag recently sent a check for $5,000 to St. George's Hospital, London, and its receipt was acknowledged with thanks. But upon presentation of the check at the bank it was ascertained that the donor had no account there.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 25 to May 1, 1886.

CORSON, JOSEPH K., Captain and Assistant Surgeon. Granted ten (10) days' extension of leave of absence granted in Orders No. 79, April 15, 1886, Jefferson Barracks, Mo. S. O. 97, A. G. O., April 26, 1886.

WILSON, WM. J., Captain and Assistant Surgeon (Platts-burg Barracks, N. Y.). Granted leave of absence for one month on surgeon's certificate of disability. S. O. 25, Division of Atlantic, April 27, 1886.

BENHAM, ROBERT B., Captain and Assistant Surgeon. Ordered from Department of Texas to Department of Dakota. S. O. 97, A. G. O., April 26, 1886.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 1, 1886.

WILBER, F. W. F., Assistant Surgeon. Detached from R. S. Vermont, and ordered to the Hartford.

TRACY, ELMER C., Assistant Surgeon. Ordered to the Vermont.

WAGGENER, J. R., Passed Assistant Surgeon. Detached from the Hartford, and ordered to the Iroquois.

BRANSFORD, J. F., Surgeon. Detached from the Iroquois, to proceed home and await orders.

KITE, ISAAC W., Assistant Surgeon. To duty at Naval Hospital, Brooklyn, N. Y.

May 1, 1886.....	0	0	9	7	1	30	1	0

BINIODIDE OF MERCURY.—The great drawback of the employment of the biniodide of mercury as an external application consists in its insolubility. M. Méhn, Member of the Academy of Medicine in the Pharmaceutical Section, has overcome this difficulty by recommending the salt to be rubbed up with castor-oil, which completely dissolves it. A solution of one part of the salt to fifty parts of castor-oil does not become cloudy. This solution is sufficient to satisfy the exigencies of therapeutics. The addition of iodide of potassium increases the solubility of the biniodide of mercury in castor-oil.—Paris correspondent of *The American Practitioner and News.*

SPONGE MUSTARD-PLASTERS.—Richardson makes use of a simple sponge, dipped in a mixture of flour and mustard, whenever it is desired to apply a sinapism. The sponge, filled with mustard paste, is covered with a moist handkerchief and applied to the part. The same sinapism may be reapplied three or four times without renewing the mustard, simply warming the sponge. When the application is no more desired, the sponge may be washed in warm water, and is then ready for any other use.

DIABETIC COMA FROM A CLINICAL STANDPOINT.[1]

BY ROBERT J. DEVLIN, M.D.,

ASSISTANT PHYSICIAN [illegible]
INSTRUCTOR [illegible]

I INTEND, this evening, to consider a group of symptoms, usually associated with the more severe types of glycosuria, and forming the terminal phenomena in a large percentage of the fatal cases, at least in recent years.

It derives a special interest from the obscurity which surrounds its origin, its, for the most part, unsuspected onset, and the tragic course of symptoms toward a death which seems to be but rarely averted when once the condition has advanced to the stage of coma.

Broadly speaking, we understand by the term diabetic coma a series of symptoms occurring in a patient, the subject of glycosuria, of which the most characteristic are a more or less sudden failure of vital strength, a peculiar dyspnœa, and a condition of mental hebetude tending to progress into fatal coma.

It is certainly remarkable that while diabetes mellitus and its fatal tendency have been clearly recognized by the profession for over two centuries, it is only within the past twelve years that any special notice has been taken of these peculiar phenomena.

Cases of sudden death, preceded by coma, variously ascribed to exhaustion, uræmia, apoplexy, meningitis, etc., have been reported often enough; but details as to the terminal symptoms are scanty, and no reference is made to those we now consider most characteristic Even when an autopsy was made they are briefly dismissed with the comment that no lesions were found, with the naked eye, sufficient to account for death.

In 1874 Kussmaul[2] published three cases, possessing certain features in common, which exhibited a mode of fatal termination till then undescribed.

Since then a considerable literature has grown up on this subject, and a large number of more or less carefully recorded cases have been reported.

Perhaps, very properly, the pathological has taken precedence of the clinical discussion, but thus far with singularly barren results. At present we have no theory which will satisfactorily explain even a respectable minority of the cases.

It is my purpose to avoid, as far as possible, all reference to disputed pathology, and confine myself to the following clinical features of this so-called complication of glycosuria, in the endeavor to ascertain from the published cases: the class of diabetics most apt to fall into fatal coma; the various causes which seem to produce or precipitate it; the premonitory signs, if there be any of value in predicting its appearance; the onset and course; and subsequently to consider—the occurrence of abortive attacks, and the prophylactic care and medical treatment best suited to limit such cases.

In endeavoring to collect cases from which to obtain data there have been several sources of difficulty.

With the time and facilities at my disposal it has been impossible to collate all the published cases.

When references had been laboriously hunted through the various journals to their original source, they often proved entirely useless for the purpose intended. In many, from failure to mention the presence or absence of certain symptoms, or to note the condition of the chief viscera, the diagnosis was doubtful. In some nothing but the lethal symptoms are given. In others only facts bearing on certain pathological theories are stated. And in the great majority the details, when given, are expressed in such general and indefinite language as to defy any attempt at tabulation. Certain other groups are summarized, often with great clearness, but the individual histories are not accessible.

Even a superficial examination of the fatal cases shows such a wide range of difference in their phenomena that it is desirable, for the sake of clearness, to divide them into various groups, without, however, of necessity implying any essential difference in their pathology.

The division found most convenient is very nearly that adopted by Frerichs.[1]

The first class comprises those which are characterized mainly by sudden onset of collapse symptoms, followed speedily by coma and death.

There seems to be nothing, either in the age of the patient, the duration of the disease, the intensity of the symptoms, the previous medication, diet, or general nutrition of the patient, which specially predispose to this form. The majority of the patients had apparently been doing tolerably well, showing no marked signs of exhaustion or impending heart failure; nearly all of them had been able to be up and about until the seizure; in several cases there is nothing to show that the patients considered themselves invalids; in two cases the diagnosis of diabetes mellitus was only made by post-mortem examination of the urine; sometimes the attack has come on during a period when all the morbid symptoms were improving rapidly.

The exciting cause has usually been some unwonted physical exertion or a long journey. In one case—a patient for some time confined to the hospital ward—it followed great mental depression from the receipt of bad news.

There are usually no premonitory signs; the patient is seized with symptoms closely resembling those of surgical shock, preceded by a sudden profound exhaustion.

There is no pain, very rarely vomiting, no dyspnœa of the kind described by Kussmaul, although the respiration may be somewhat hurried and superficial. The pulse is very feeble and flickering.

There is nothing that can fairly be called a stage of delirium. The patient is rather apathetic, even while still able to answer questions. In a short time he becomes absolutely comatose, and death follows usually within a few hours.

In none of the reported cases is there any mention of an ethereal odor to the breath, or any reaction of the urine with ferri chloridum, such as will be spoken of later, although several are reported by observers who in other cases have noted these phenomena.

The indications as to prophylaxis are obvious enough, but unfortunately there seems to be no way by which to distinguish such cases in advance from those which live for years, enduring the ordinary fatigues and excitements of daily life, to which certain others succumb so readily.

Perhaps systematic physical examination of the condi-

[2] Deut. Archiv f. klin. Med., xiv., 1.

[1] [illegible]

tion of the heart and the use of the sphygmograph should be a routine procedure in diabetes, and the indications thus afforded may prove of value; but I have been unable to find any observations bearing on this subject.

It is not at all evident that the class of cases above mentioned have much in common with the variety described by Kussmaul, and to which perhaps the term diabetic coma should be restricted.

In all exhausting diseases which profoundly modify the conditions of nutrition, terminal phenomena are occasionally met with which are scarcely distinguishable from the above, except in the one feature of glycosuria. Sudden death from contracted kidney, with so-called uræmia, might be instanced.

By far the greater number of cases of diabetic coma fall into the second class, and exhibit phenomena having a remarkable likeness to the effects of an organic poison.

If we seek to discover the predisposing causes which influence—or, perhaps more accurately stated, the conditions which precede and appear to influence—the occurrence of this form of sudden death in diabetes, we shall enter upon a task of exceeding difficulty; for no statement can be made which is not challenged by numerous recorded exceptions.

Nevertheless there are certain factors which are sufficiently constant to give them a considerable value in prognosis.

Systematic treatises on diabetes recognize two types of the non-symptomatic cases. One is characterized by an ability on the part of the organism to assimilate at least a small amount of carbohydrate food. Such are free from glycosuria and its attendant evils when the diet contains a minimum quantity of such elements. Hence they are to a certain extent amenable to treatment. The other class of cases excrete sugar in excess of the quantitative equivalent contained in the food, and even when such elements are entirely withdrawn. These latter tend to every variety of fatal termination with much greater rapidity than the former.

This division, while convenient and of great clinical importance, is nevertheless quite artificial, for many cases pass from one to the other form at different periods of their history, and but few are observed with an accuracy which gives much confidence in the results stated. However, it would seem that death by coma is a more frequent termination in the severe than in the mild types; at all events such is noted in those which are under continuous treatment.

In a large number which have come under observation but a few days before the onset of coma, and in which rigorous treatment was adopted at once, the sugar has suddenly disappeared—its disappearance being shortly followed by grave symptoms. Of course, we are in doubt whether to class such cases as of the first type, or to attribute the disappearance of the sugar to the same unknown cause which determines the coma. Especially when we see that in certain cases under close observation but very lax dietary, the same diminution or disappearance of both the glycosuria and the polyuria has also preceded the fatal symptoms.

This subject will again be referred to in discussing the effect of diet.

The element of age has always been regarded as very important, namely, the younger the patient the more likely is death by coma.

Mackenzie,[1] in analyzing thirty-seven consecutive deaths from diabetes in the London Hospital, remarks, that with one exception all dying under the age of twenty-five years died of coma. Dreschfeld,[2] in an analysis of fifty cases, the details of which I have not been able to find, remarks that it occurs chiefly in early life. I have tabulated ninety-eight cases in which a definite statement is made as to the age, and find that the average is twenty-nine and two-thirds years. And in twenty-two other cases in which no exact statement is made, eight are designated as adults, nine as young, one each as middled-aged, boy, and child, and in two no hint is given. The extremes are a case reported by Dr. Schmitz, of Neuenahr,[3] aged seven years, and one reported by Dr. Quincke,[3] aged sixty-two years.

For comparison I have computed the average age of the fatal cases from all causes given in the clinical appendix to Siegen's[3] treatise on Diabetes, and those given in a table of all the deaths which occurred in New York City from diabetes, during a period of three years and three months, taken from a paper read before this Academy by Dr. Gouverneur Smith[4] in 1871, giving a total of ninety-five deaths and an average age of forty-nine years. No cases are included in both lists.

Any statement as to the duration of the disease is open to serious doubt, since the early history of diabetes is in general made up of very indefinite symptoms, and the diagnosis is rarely made until the condition has existed for some time. The histories I have examined afford very little information that is worth stating in figures. Nevertheless it is quite evident that as a class comatose cases are those which present an acute invasion and rapid progress of the usual diabetic symptoms. Southey[5] reports a case in which polyuria was suddenly developed two weeks before the patient—a girl, aged seventeen—came under observation; five days later death ensued by coma.

I have seen a case of still shorter duration, in which only sixteen days elapsed between the sudden onset of polyuria and the fatal termination. This patient was a boy, twelve years of age, who came under observation only two days before death, and after the onset of the comatose attack. He had not been under treatment, and from the time he was first seen the anorexia was complete. With these may be contrasted the case reported by Quincke, and referred to above, in which the patient was a man, aged sixty-two, diabetic for ten years, during which time the disease was held in check by dietetic treatment. He died within twenty-four hours after the onset of the attack, which, we are led to infer, was the result of excesses in diet, although this is not explicitly stated.

In these cases we have illustrations of extreme variations of age of patient, duration of the disease, and severity of type, with a similar mode of termination.

Pavy,[6] Taylor,[7] and others, call attention to the fact that those cases which terminate in coma are in all but a few instances free from pulmonary complications, or, at any rate, are free from the rapid form of phthisis frequently termed diabetic.

On this point the following statistics may be given: In 133 cases the lungs were stated to be normal in 82, phthisis was present in 14, pneumonia in 7, bronchitis in 2, pleurisy with effusion, 1. In 27 no record was made.

These figures are in part drawn from physical examination and in part from accounts of autopsies, when such were given. Of course the accuracy of the former data may be questioned. The following are those based on autopsies—bronchitis, pleuritic thickenings, hypernæmia, and œdema of the lungs being accounted as negative: Pulmonary changes found in 30; lungs normal in 30. In 45 unselected autopsies of diabetics given by Siegen the lungs were found to be normal in only 12, judged by the above standard. In by far the greater number of cases the patients exhibited the usual symptoms in a well-pronounced form. Emaciation and failure of strength had generally advanced to a profound degree, although there are exceptionally cases which showed very little depreciation of the general health and body-weight.

Many were capable of active exercise, and even hard work, up to the last few days, or, in some cases until the actual onset of the symptoms. In a few the general health had continued so good that the diagnosis was only made post-mortem.

Observations as to the occurrence of albumen and casts in the urine, and the results of minute post-mortem examinations of the kidneys are not sufficiently numerous or systematic to warrant any general statement. In cases in which any record is made of the presence or absence of albuminuria before the attack, it is more frequent to record its absence. When albumen, in any notable amount, and casts have been found in cases of diabetes which terminated in coma, it is usual to state that the death was by uræmia, chronic Bright's disease, nephritis, etc., and to omit all details.

Hence we may infer that in cases reported as diabetic coma these appearances have not been present, or perhaps have not been looked for. More accurate observation in all cases of glycosuria is needed to settle this point.

The onset of urgent symptoms has been attributed to a great variety of exciting causes, the most constant of which are sudden fatigue or nervous excitement, intercurrent disease—particularly of a suppurative or gangrenous character—bronchitis, injudicious use of opium, insufficient supply of fluids, and lastly, errors in dietetic management.

Certain other elements, such as gastro-intestinal disturbances, neuralgias, and the like, may be regarded either as exciting causes or merely as prodromal symptoms. There are other cases which arise in the absence of any assignable cause, and when the patient's condition and environment have undergone no recent changes.

Of all the causes above mentioned, fatigue has been set down in the greatest number of cases, and yet the more closely we analyze the circumstances the less satisfactory will appear the reasons.

There seems no doubt of its potency in the class of cases first mentioned, in which the clinical picture is simply heart failure and collapse; but in those we are now discussing we must look further for the causes to which fatigue or mental excitement may act as an adjuvant. A journey to a hospital or to see a celebrated physician is shortly followed by bad symptoms. But patients in chronic diseases, as a rule, do not enter hospitals or undertake long journeys to consulting physicians or health resorts until symptoms arise which lead them to lose confidence in their former advisers. How many histories begin with: "While feeling tired and out of sorts he undertook to walk," etc.?

When we consider that patients are apt to set a higher value than their physicians upon the presence of vague symptoms, such as malaise, general tired feeling, loss of appetite, oppression about the chest, which often are the first premonitory symptoms, we can easily believe that these have been underestimated by the reporter who states that the patient left home in his usual health. When the connection between fatigue and coma seems unquestionable, the sequence is almost immediate. In many of the cases the physical exertion assigned as the cause is so slight that, if we ascribe much importance to this factor acting by itself, we may do harm by forbidding the exercise which is so helpful to the proper assimilation of a highly nitrogenous and at the same time superabundant diet.

Indeed Jaenicke[1] is disposed to attribute the relative frequency of nervous complications in those cases which are observed in hospital practice to the fact that the lack of exercise, combined with an exclusive animal diet, forming a sharp contrast to the previous mode of life, leads to faulty metabolic action.

However, fatigue as well as nervous perturbations, and perhaps more justly surgical injuries, carbuncle, alveolar abscess, suppurative otitis, gangrene, bronchitis, and the like, may be said to precipitate an attack of impending coma in the same way that similar accidents may precipitate uræmic phenomena.

Some of the English authorities have set down the use of opium and its analogues in the list of causes.

Dickenson[2] believes that opiates exert an injurious influence by favoring dyspepsia and constipation.

Fagge[3] believes that opium, used to control diarrhœa or pain, can be held responsible for some of the deaths.

However, since the opiates were used to combat symptoms which we shall soon see may belong to the first stage of the attack, and since the subsequent progress of the cases differed very much from opium narcosis, I think that we need not be deterred from a cautious use of the only remedy which will relieve the agonizing pain so often present.

The effect of diet can be more conveniently discussed in a later section.

The premonitory symptoms are very varied. Sometimes for a period of weeks the patient will have mild dyspeptic symptoms, alternating with periods of improvement. The appetite is almost always markedly lessened; any reduction below the standard for a healthy person should be looked upon with suspicion. The patient who has been constipated begins to have unexplained loose movements, sometimes a profuse diarrhœa; or the bowels, previously tolerably regular, become obstinately constipated. Especially during the latter condition a peculiar odor to the breath is developed, which has been variously likened to decaying apples, sour beer, chloroform, etc. In these early stages it is never very pronounced, but during the fully developed attack often pervades the whole vicinity of the patient, and even extends to adjoining rooms. Acid eructations and nausea, with or without vomiting, are sometimes noted. Accompanying these gastro-intestinal symptoms there is often a peculiar sense of general prostration; the patient is disinclined to all exertion, physical or mental. There is a tendency toward drowsiness during the day, and the patient is often very despondent. Attacks of intense vertigo, frontal headache, neuralgic pains in various regions, are quite common.

A very constant symptom is an accelerated pulse, with or without decrease in volume.

The urine is usually diminished and the percentage of sugar reduced. An increased acidity has been noted. In a large number of cases, even during this stage, the urine strikes a reddish-brown color on the addition of ferric chloride.

Sometimes, when the amount of urine, the percentage of sugar, and the excessive appetite are suddenly reduced, with the other premonitory signs but slightly marked, the change is attributed to successful treatment, which notion is rudely dispelled by the speedy onset of cerebral symptoms.

Any sudden improvement in the objective signs which is not confirmed by the subjective sensations of the patient should put the physician on his guard.

After a variable period of such indefinite symptoms as have been described, the patient begins to complain of a feeling of depression, is restless at night, eats nothing; if constipated, takes the usual laxatives without result, complains of colicky pains through the abdomen, which may be distended with gas, or perhaps retracted. There is a sense of constriction about the thorax which causes the patient to breathe more deeply than usual. He vomits from time to time, usually in connection with paroxysms of epigastric pain, but without obtaining relief. The vomited matter is usually scanty and greenish, often having the peculiar odor of the breath. The patient tosses about in bed; if able to be up is unsteady in gait. Sometimes the vertigo is too intense to allow him to rise from a horizontal position, although the muscular strength may be sufficient.

[3] Guy's Hosp. Rep., vol. xix.

The mental condition varies from excitability to mild talkative delirium, alternating with drowsy or stupid intervals. Even during the latter the patient can be readily aroused to take drink or medicines, and will answer questions in a dazed sort of way.

When he rouses spontaneously, it is usually the result of a paroxysm of abdominal pain which causes him to cry out. Examination of the abdomen fails to give any adequate explanation of this symptom.

Gradually the intervals of consciousness become fewer and shorter, and the patient lies quietly, with partly closed eyes, and can only be roused by loud noises or violent shaking. Finally the coma becomes unbroken, although in a few cases the patient has had brief returns to consciousness, during which he has been able to answer questions with a certain degree of intelligence shortly before death.

When coma is once fully established, the power of swallowing fluids is usually lost. In a few cases there have been convulsive twitchings of the facial muscles at the time of death. I can only find three cases in which there were general convulsions. One, a typical case in other respects, reported by Dr. Murrell;[1] another, reported by Dr. Fürbinger,[2] in a case in which, some time before death, the glycosuria was replaced by oxaluria of high intensity, the patient dying with symptoms resembling diabetic coma, but considered by the author as due to oxalic-acid poisoning; and a third, reported by Dr. Schmitz,[3] in a child, aged thirteen, in which the gastric symptoms were especially pronounced.

During the progress of these cerebral symptoms, and often preceding their full development, there is the peculiar dyspnœa so frequently alluded to. Its characteristic feature is an exaggerated respiratory effort, independent of the patient's volition, and not due to any obstruction to the entrance or exit of air to the lungs, or the free access of air to the pulmonary vesicles.

Cyanosis is slight or entirely absent. The respirations are generally quickened, but regular at first, and later in the progress of the case both the frequency and the depth of the inspirations may undergo a rhythmical variation similar to that known as Cheyne-Stokes.

The expiration has an expulsive character, amounting to a sigh, from time to time intensified to a loud groan.

The accessory muscles of respiration are all brought into play, and the picture resembles that of an unexperienced runner after a sharp spurt.

During the attack the quantity of urine secreted is almost invariably diminished. Occasionally there is complete suppression. During the stage of coma retention is usual, sometimes incontinence, which will frequently be found due to overflow.

The amount of sugar in cases in which careful record has been kept is found to be markedly reduced, often absent.

Albumen in small quantity is usually, but not invariably, detected.

In all but a few of the cases in which the test has been made, the reaction with ferri chloridum is observed.

In a smaller number of cases a peculiar odor to the breath develops, which has been so differently described as to lead to the belief that it is not the same in all cases. It was present in each of the three cases I have seen, and closely resembled the odor produced by shaking up a small quantity of chloroform with a few drops of acetic acid in a little water.

With the exception of the muscles of deglutition, no paralysis seems to have been noted. In one of my cases there was marked rigidity of the muscles of the lower limbs, separation of the knees requiring all the force I could exert; when released they slowly returned to firm adduction. Flexion and extension at the knee resisted, but not so strongly.

The condition of the pupils is not characteristic. The absence of patellar reflex is often noted, but this probably belongs to an earlier period of the disease.

Cutaneous anæsthesia seems to be quite common.

The temperature, in the absence of complications, is generally subnormal. In one case I have watched it rise from the normal at the beginning of the attack to 106.4° F. in the axilla, the last record being made one hour before death—the total duration of the pyrexia being about twelve hours. No complication was detected by careful and repeated examinations.

A certain number of cases exhibit a mode of onset and course which differs in so many respects from the above type that Frerichs assigns them to a separate class. They are characterized by a comparatively sudden onset; there are no premonitory symptoms that are sufficiently definite to deserve mention; they are preceded at a short interval by a more or less obvious cause, such as a carbuncle, a gangrenous toe, or the patient is seized immediately after some violent exertion or excitement, running to catch a train, or an outburst of anger, for example. The first symptom is usually headache or vertigo, followed by a condition so closely simulating alcoholic intoxication that the majority of cases have been mistaken for drunkenness until investigated. The patient passes rapidly into a stupid condition, merging into fatal coma. There may be no dyspnœa, nor are the pulse and muscular strength so notably affected at the outset as in the other variety.

I do not think that this class deserves an extended description. The type is ill-defined, and but few examples can be found which conform to it. In the ordinary form exceptional cases are met with in which dyspnœa is not well marked, and the pulse remains fairly good until just before death. In a great many cases the delirium has been noted as resembling alcoholism.

I have recently had charge of a case which presented some unusual features which merit being put on record.

The patient, a boy, aged sixteen years, whose family history is exceptionally good, had suffered from occasional incontinence of urine for about three years.

There does not appear to have been any actual polyuria, and with this exception he seemed to be perfectly well until about ten months before his death, when, without any history of traumatism, or any obvious cause, unless perhaps an immoderate indulgence in athletics, he began to fail in health, and was noticed to pass an increased quantity of urine. About five months later, these symptoms having meanwhile slowly increased, he became much worse, apparently as the result of a day of excessive fatigue and excitement. At its close he was seized with severe cramps in the legs, which lasted all night; and the flow of urine suddenly rose to twenty pints. Examination of the urine being now made for the first time, sugar was detected. After a period of several weeks, during which he was not under treatment, and in which the ordinary symptoms of severe glycosuria developed, he was put on strict diet, continued for six weeks, but without any improvement.

From that time ordinary bread, to the amount of several ounces daily, was allowed, but in other respects a pretty strict diet was maintained.[4]

For three months previous to the time I first saw him he had been taking a secret remedy, which apparently consisted of salicylate and bicarbonate of soda, with bitter tonics, acid drinks, and a considerable quantity of glycerine daily. During this period there was nothing special to note except a gradual failure of flesh and strength. The amount of urine remained as before, until three weeks before my first visit, when it suddenly diminished to a daily average of ten pints, and exhibited very marked fluctuations from day to day. On examination I found him extremely emaciated, his weight having been reduced at least one-fifth from his former standard. Had voracious appetite and great thirst, dry skin, a few small furuncles; caries of the teeth, several of which are loose; no odor to breath except a slight sweetish quality; axil-

lary temperature, 96⅕° F.; heart and lungs normal to physical examination; myoidema very well marked; pulse, 108.

Examination: Urine 1.036, very strongly acid, no albumen; sugar, thirty-two grains to the ounce; passed one hundred and sixty ounces in the twenty four hours. Microscopic examination negative. In view of the gloomy prognosis which I gave, the family asked to be allowed to continue the remedies already in use. For some symptom which I do not now recall, I prescribed am. bromid., gr. xv., t.i.d. During the next week the urine averaged one hundred and fifty-three ounces daily, but with wide daily fluctuations. Several examinations showed the percentage of glucose—six and one-half—to be pretty constant.

At the end of this week I was called to see him again, and found that he had been suffering from a small alveolar abscess, which had kept him in a restless condition. This was now discharging freely. He also complained of supra-orbital neuralgia on one side, which had kept him awake during the first night. Stopped am. bromid. Calx sulphid., gr. ¼, 5 in diem.; codeia, gr. ¼, t.i.d. Examination: Urine one hundred and forty-four ounces, 1.031, specific gravity; sugar, twenty-six and one-half grains to the ounce, no albumen; reacts to ferri chlorid. feebly, which was at that time attributed to the salicylate which patient was taking, and which was then ordered to be discontinued. Three days later I was called again, and found that the supraorbital pain had disappeared soon after the last visit, and that he had been tolerably comfortable, although very weak and disinclined to eat, until eleven o'clock the previous night, when he was suddenly seized with severe pain in the left hypochondrium. Bowels have not moved in two days. Customary dose of compound licorice powder given yesterday has had no result. Urine in last twenty-four hours one hundred and forty-four ounces.
